Chapter pages in book: (p. 211 - 240)

# The Simultaneous Effects of Obesity, Insurance Choice, and Medical Visit Choice on Health Care Costs

Ralph Bradley and Colin Baker

# 7.1 Introduction

Several studies suggest that obesity increases health risk and health care spending. A publication from the National Institute of Health (1999) cites over 600 medical studies showing that obesity increases the risk of various diseases such as diabetes, stroke, and heart disease. Three examples of studies concluding that obesity increases health care costs are Cawley and Meyerhoefer (2012), who conclude "that obesity raises medical costs by \$2,741"; Thorpe, Florence, and Joski (2004); and Finkelstein, Fiebelkorn, and Wang (2003).

Most studies of the effect of obesity on health care costs treat obesity and body mass index (BMI) as exogenous.<sup>1</sup> However, Cawley and Meyerhoefer (2012) recognize that BMI could be an endogenous right-side regressor, and use instrumental variable estimation. Their instrument is the BMI of biological children, and thus their study is limited to adults with biological children. In addition, they estimate a two-part model for medical expenditures. In the first part the probability of a nonzero medical expenditure is estimated, and in the second part a gamma regression with a log link function is estimated. Insurance status is treated as exogenous.

Other studies estimate the dollar-equivalent cost to the obese from lifeexpectancy loss. Others attempt to investigate the incidence of obesity costs

1. Body Mass Index is derived as (Weight in Pounds/[Height in inches]<sup>2</sup>)703. The obesity threshhold is a BMI over 30.

Ralph Bradley is division chief of Price and Index Number Research at the Bureau of Labor Statistics. Colin Baker is social science analyst at the US Department of Health and Human Services, Office of the Assistant Secretary for Planning and Evaluation.

(i.e., who bears the cost—the obese individual or the obese individual's employer). See Bhattacharya and Sood (2011) for a review of this literature. Like Cawley and Meyerhoefer (2012), we focus on annual per capita costs.

Despite all the evidence of obesity's adverse health effects and numerous public and private efforts, obesity rates continue to rise. This contrasts with the substantial success at reducing US smoking rates. It is difficult to find reasons that obesity rates continue to climb even though it increases the risk of many diseases. We try to do this with a simple micromodel of BMI choice. It has latent variables observable only to the individual that influences preferences when BMI, insurance, and medical visit choices are set. The model predicts that the individual will take into account the BMI choice when making the insurance choice. The endogeneity coming from the latent variables and simultaneously determined choices creates inconsistent estimates unless this endogeneity is properly treated.

Several studies explain the obesity problem through the use of behavioral economics. Ruhm (2012) models weight choice as an interaction between a deliberative (rational) system and an affective system where the weighting of the two systems is a function of an exogenous endowment of "selfcontrol." Cutler, Glaeser, and Shapiro (2003) suggest that obesity can occur from nonrational discounting of the future benefits of dieting. These behavioral economic models are appealing because they are consistent with a neuroscience-based explanation. The difficulty with such models is that there are so many latent variables, such as self-control and the irrational discount rate, that they are hard to verify empirically. We argue in this study that disutility occurs when reducing BMI and the marginal disutility per unit of BMI reduction is randomly distributed across the population. This disutility could easily be a function of an individual's neurotransmitter system, metabolism, access to healthy food, and income/leisure resources to access gyms and weight clubs. While Cawley and Meyerhoefer (2102) emphasize genetics, we argue that genetics is at best only a part of the cause of obesity. Body mass index is still the result of choices. We use a simple micromodel to show that an unhealthy BMI could be a rational maximizing choice where the individual trades off the increased disutility of weight reduction with the increased utility coming from better health. Such a model is still consistent with the behavioral economic approach, and it provides a better guide for econometric specification of structure because it shows where and how the endogeneity occurs.<sup>2</sup>

In this study, instead of always using instruments to correct for endogeneity of BMI, we use control variables as outlined in Newey, Powell, and

<sup>2.</sup> Our micromodel is consistent with the explanation given by the Centers for Disease Control and Prevention. Their website says, "Body weight is the result of genes, metabolism, behavior, environment, culture, and socioeconomic status." See http://www.cdc.gov/obesity /adult/causes/index.html.

Vella (1999). Unlike Cawley and Meyerhoefer (2102), we do not use a twopart model, but instead estimate a multiple-selection tobit-type model that allows for the possibility that when consumers set their BMI and insurance status, and decide whether to visit a provider, latent variables are common to all these choices. If this is true, then the two-part model with exogenous insurance does not provide consistent estimates. Our methods are based on a two-period (ex ante and ex post) microeconomic model adapted from Dragone and Savorelli (2012). Their model recognizes that getting one's BMI (through consuming calories below the level of satiation) nearer to an ideal level invokes disutility, and when setting BMI, the consumer must trade off the marginal utility of additional health with the marginal disutility of feeling increasingly unsatiated.<sup>3</sup> In our model, both insurance status and BMI are simultaneously set ex ante. After a draw of a random health status variable in the expost period, the consumer chooses whether or not to visit a service provider. If the consumer visits a provider, then based on the consumer's health status, the provider selects a treatment intensity.

This study uses data from the Medical Expenditure Panel Survey (MEPS). One limitation of MEPS data is that if individuals visit a provider such as an emergency room and the provider receives no payment, then the expenditure is recorded as a zero even though the treatment had an actual cost. Unlike previous studies, this study adjusts for uncompensated care. Another challenge is that not all MEPS respondents answer the height and weight questions, introducing possible bias if BMI is a consideration in not responding.

We use eight years of MEPS data from 2002 to 2010. This is a very interesting period to study obesity. During this period, MEPS shows that the national obesity rate continues to climb despite a rise in food prices in 2008 and despite little or no change in food-processing technology as during the period of the Cutler, Glaeser, and Shapiro (2003) study. Additionally, during this period, the adverse health effects of obesity were well known. Not only is obesity rising during this period, but the diseases arising from obesity such as diabetes, hypertension, and hyperlipidemia are also rising.

We start this study with a simple micromodel that shows that unhealthy BMIs can be a result of an optimizing decision. This model predicts that there can be ex ante moral hazard from having health insurance when making BMI choices, and there can be adverse selection where those with greater propensity to have higher BMIs will more likely purchase health insurance.<sup>4</sup> In the simple micromodel, the individual has unobserved characteristics that influence the BMI, the insurance decision, the decision to visit a medical

4. If wages adjust for the expected ex post costs of obesity for all employer plans, and if individual-plan premiums adjust for expected ex post costs, then there is no ex ante moral hazard or adverse selection.

<sup>3.</sup> Their focus is on anorexia nervosa, but their micromodel can be easily adapted to obesity.

provider, and the level of medical expenditures. When these conditions exist, the two-part model will not generate consistent estimates.

Since we wish to test the ex ante moral hazard and adverse-selection predictions of the model, we can only do this when individuals have a health insurance status choice. We therefore limit our analysis to adults who are not eligible for any public insurance program and are free to choose whether or not to be insured.

When we run simulations to estimate the impact of an exogenous reduction in BMI on costs, we use our model first to estimate the effects of BMI change on propensity to insure and propensity to visit a provider. Our final estimate on cost is the sum of the cost impacts due to changes in propensity to insure, medical visitation propensity, and the direct effects on costs. The Cawley and Meyerhoefer (2012) estimates only incorporate the visitation-propensity effect and the direct effects on costs.

Unlike previous studies, we account for the endogeneity of BMI by explicitly modeling and estimating BMI choice.<sup>5</sup> Other previous studies have not been concerned with the individual's trade-off between the health benefits of a lower BMI with the increased disutility of making the effort to reduce BMI.<sup>6</sup> Since this disutility of effort or BMI outcome cannot be written into an employer-sponsored insurance contract (noncontractible) nor can employer-sponsored plans risk-adjust premiums for the marginal actuarial cost of a marginal increase in BMI, we cannot get a "first-best" allocation of this disutility. (This is the reason for the ex ante moral hazard).<sup>7</sup> If genetics is the key factor behind BMI determination, and individuals do not choose their own BMI, then there is no ex ante moral hazard.

We get many interesting empirical results. First, we find evidence that the nonignorable response for the MEPS weight question is most likely for individuals with BMIs between 27 and 30. They are not fully obese, but there is a possibility that it is difficult to assess their weight by appearance. The obese are more likely to report their weight. Second, we find that food prices have no statistically significant effect on BMI choice. Third, we find that an increase in

5. There are other studies in other areas of obesity that also do not account for the endogeneity of obesity. Bhattacharya and Bundorf (2009) estimate the incidence of obesity by running an ordinary least squares (OLS) equation with wage as the dependent and obesity dummies as an exogenous regressor. They get unexpected results, such as a positive parameter estimate for the employer-sponsored insurance dummy. Many of their obesity parameter estimates are negative, but not statistically significant.

6. We focus on the disutility of BMI reduction because possibly intervention programs misestimate this disutility and make weight reduction sound easier than it is. When participants find that BMI reduction is not as easy as they were led to believe, they might get discouraged and drop out.

7. Bhattacharya and Sood (2006) focus entirely on this source of ex ante moral hazard, but they do use these words. Instead, they use the words "obesity externality." Even for individual plans, a marginal BMI addition to premiums can be problematic. Bhattacharya and Bundorf (2009) find that wages for employees with employer-sponsored plans do adjust for BMI effects. In this case, there is no ex ante moral hazard or adverse selection.

BMI will increase the propensity to purchase health insurance (adverse selection) and the presence of insurance has a positive effect on BMI choice (ex ante moral hazard). This confirms the predictions of our micromodel. Fourth, there is evidence that there are common latent variables that the researcher cannot observe when individuals make the medical utilization and insurance choices. Thus, correct modeling requires either the use of instrumental or control variables. The fifth finding is not directly related to the effect of obesity on costs and is counterintuitive. Those who have a high propensity not to visit providers, on average, create more cost because when they are induced to see a provider their illness has become far more severe, and this severity could have been prevented had they seen a provider earlier. Since a higher BMI increases this visit propensity, obesity's effect on this propensity generates a small cost savings. We argue that the Cawley and Meyerhoefer focus on the cost of obesity is the wrong focus. However, we find that obesity only increases costs by \$430.33 compared to their \$2,741. If each obese individual reduces BMI by 10 percent, on average there will only be a \$45.28 reduction in medical costs. The cost elasticity of obesity is only .0115 percent.

Section 7.2 establishes the microfoundations for the econometric model in this study. Section 7.3 describes the data and estimation methods, and section 7.4 describes the results.

#### 7.2 A Simple Micromodel

Several microeconomic studies employ behavioral economics to explain the presence of obesity. Such studies are Ruhm (2012) and Cutler, Glaeser, and Shapiro (2003). In this study, we argue that obesity can be the result of a rational utility-maximizing process. Our micromodel is borrowed from Dragone and Savorelli (2012). While their concern is with anorexia nervosa, it is still useful here because it accounts for the disutility of consuming calories below (or above) a level of satiation. Since body weight is a monotonic function of calories consumed, choosing a calorie consumption is equivalent to choosing a BMI. Therefore, unlike Dragone and Savorelli, we focus solely on the BMI choice.

There are two periods—ex ante and ex post. In the ex ante period, the consumer makes expectations on her health status and medical spending in the ex post period. Based on these expectations the consumer decides her insurance status (denoted as  $I_i$  where *i* indexes consumers), and her BMI (denoted as  $B_i$ ). If the individual decides to buy insurance then  $I_i = 1$ , otherwise it is 0. Cost sharing, respectively, under insurance and no insurance is  $c_{I,i}$  and  $c_{N,i}(c_{I,i} < c_{N,i})$ .<sup>8</sup> The ideal BMI (denoted as  $B_i$ ) does not vary. However, there is a "natural" BMI (denoted as  $B_{N,i}$ ), which occurs when the individual eats to

<sup>8.</sup>  $c_{N,l}$  can be less than one. Often an uninsured individual can visit a provider and pay nothing for the service. This is particularly true of emergency room visits.

satiation and pursues no other activity to manage weight;  $B_{N,i}$  varies by individual. The lower the individual's  $B_i$  goes below the satiated BMI,  $B_{N,i}$ , there is an increasing marginal disutility of nonsatiation. The econometrician cannot observe  $B_{N,i}$ . When forming expectations, there are characteristics observable by the econometrician (denoted as  $X_i$ ) and other unobservable characteristics (denoted as  $\xi_i$ ) that help predict the ex post health status (denoted as  $S_i$ ).<sup>9</sup> When the ex post period begins, the consumer draws an unpredictable shock,  $\varepsilon_i$ , and the log of the health status variable is determined by<sup>10</sup>

(1) 
$$\ln(S_i) = \beta_0 + X_i\beta_1 + (|B_i - B_i|)\beta_2 + \xi_i + \varepsilon_i$$

The severity of the ex post illness is measured by  $S_i$ . A higher  $S_i$  indicates a higher illness severity. After the draw of  $\varepsilon_i$ , the individual decides whether or not to visit a service provider. If the individual does visit the provider, the total cost ( $C_i$ ) is determined as:

(2) 
$$C_i = A c_i^{\alpha} S_i, c_i \in c_{I,i}, c_{N,i}, -1 < \alpha < 0.$$

In other words, after making the discrete choice of visiting the provider, total medical cost is set to equation (2). The individual's out-of-pocket cost is  $c_iC_i$ . The parameter  $\alpha$  accounts for any ex post moral hazard. The effect on utility from  $S_i$  is

(3) 
$$U(S_i) = -BS_i^{\Gamma}, \text{ No provider visit}$$
$$= -BS_i^{\Gamma}C_i^{\theta}, \text{ With a visit}, \Gamma > 2, -1 < \theta < 0.$$

Medical spending helps lessen the disutility of illness, but not fully. To ensure this, the parameter A in equation (2) is less than B in equation (3).

The individual visits the provider if the income loss, the nonmonetary cost  $(t_i)$ , and the disutility of illness after treatment is greater than the disutility of getting no treatment or<sup>11</sup>

(4)  

$$\begin{aligned} -t_{i} - c_{i}C_{i} - BS_{i}^{\Gamma}C_{i}^{\theta} > -BS_{i}^{\Gamma}, \text{ or } \\ -t_{i} - c_{i}Ac_{i}^{\alpha}S_{i} - BS_{i}^{\Gamma}(Ac_{i}^{\alpha}S_{i})^{\theta} > -BS_{i}^{\Gamma} \\ -t_{i} - c_{i}Ac_{i}^{\alpha}S_{i} - BS_{i}^{\Gamma+\theta}(Ac_{i}^{\alpha})^{\theta} + BS_{i}^{\Gamma} > 0 \\ H(S_{i}, t_{i}, c_{i}) > 0. \end{aligned}$$

The second line is derived by substituting for  $C_i$  using equation (2). At  $S_i = 0$ , there is no visit since the inequality is not satisfied. However, given the restrictions  $\partial H(S_i) / \partial S_i > 0$ , as  $S_i$  increases there will be a threshold

<sup>9.</sup>  $\xi_i$  is unobservable to the econometrician, but observable to individual *i*.

<sup>10.</sup>  $\varepsilon_i$  is completely unpredictable by the individual, and thus is independent of  $X_i$  and  $\xi_i$ . Since  $S_i$  is a function of unobserved variables, it too is unobservable.

<sup>11.</sup>  $t_i$  incorporates time costs, anxiety costs, and all other nonobserved nonmonetary costs of seeing a provider.

 $\overline{S}_i(c_i, t_i)$  where the consumer will be indifferent between visiting and not visiting the provider. If  $S_i > \overline{S}_i(c_i, t_i)$ , the consumer visits the provider. Obviously  $\overline{S}_i(c_{Li}, t_i) < \overline{S}_i(c_{Ni}, t_i)$ .

In the ex ante period the consumer chooses her  $B_i$  and  $I_i$  by forming expectations about  $S_i$  and the choice to visit the provider in the ex post period. She will simultaneously select her BMI and insurance status to maximize the expected utility in the ex post period. In terms of the variables known by the consumer, the expected utility conditional on all variables observable to the consumer can be characterized by

(5) 
$$U = U(\pi_i, c_i, X_i, B_i - B_I, B_i - B_{N,i}, \xi_i).$$

The insurance premium is  $\pi_i$  and is zero if the individual chooses not to buy insurance;  $c_i$  is the cost-sharing variable and can take on the values  $c_{I,i}$ , or  $c_{N,i}$  depending on the insurance choice. The fourth argument measures the impact on expected utility from deviating from the ideal BMI,  $B_I$ . As equation (1) shows, a greater deviation from the ideal BMI increases expected illness severity.<sup>12</sup> The fifth argument measures the disutility of deviating away from the individual's natural BMI,  $B_{N,i}$ . It accounts for the increasing disutility of nonsatiation (and discomfort of physical activity) as the consumer moves further away from her natural BMI. Let  $U_j$  and  $U_{jk}$  be, respectively, the first derivative with respect to the  $j^{\text{th}}$  argument and the second derivative with the  $j^{\text{th}}$  and  $k^{\text{th}}$  argument. Suppose that  $B_{N,i} > B_I$ , and  $B_i$  is any value between  $B_{N,i}$  and  $B_I$ , and the following holds<sup>13</sup>

(6)  

$$B_i > B_I \Rightarrow U_4 < 0, U_{44} < 0$$
  
 $B_i = B_I \Rightarrow U_4 = 0, U_{44} < 0$   
 $B_i < B_{Ni} \Rightarrow U_5 > 0, U_{55} < 0$   
 $B_i = B_{Ni} \Rightarrow U_5 = 0, U_{55} < 0$   
 $U_1 < 0$   
 $U_2 < 0, U_{24} < 0.$ 

The fourth argument of equation (5) is maximized when  $B_i = B_I$  for any fixed values of the other arguments The fifth argument is maximized when  $B_i = B_{Ni}$  for any fixed values of the other arguments. Since  $B_{N,i} > B_I$ , if the consumer reduces  $B_i$  there is marginal increase in utility from the fourth argument,

<sup>12.</sup> An increase of  $B_i$  away from  $B_i$  increases  $S_i$ . Equation (3) gives the reduction in utility from this additional severity, and equation (4) gives the income loss from increased medical expenditures. There could be other sources of utility loss such as reduced income from productivity losses and nonmonetary costs of increased social disapproval. Bhattacharya and Sood (2006) give more detail than this study on the results of income loss from productivity loss.

<sup>13.</sup>  $U_{24} < 0$  occur because as c increases, the ex post financial impact of a higher level from illness resulting from the increased BMI increases. If wages adjust for the actuarial cost of increased BMI, then  $U_{2,4} = 0$ .

You are reading copyrighted material published by University of Chicago Press. Unauthorized posting, copying, or distributing of this work except as permitted under U.S. copyright law is illegal and injures the author and publisher.

but a marginal decrease in the fifth argument. For a fixed insurance status, when the consumer selects  $B_i$  and  $B_{N,i} > B_I$ , there is a trade-off between all the benefits coming from improving health and suffering the disutility of deviating from the natural BMI.

Given the conditions in equation (6), it is easy to see that if  $B_{N,i} > B_p$  then optimal  $B_i$  choice will be in the strict interior of the interval,  $[B_I, B_{N,i}]$ . To see this, for any  $\pi_i$ ,  $c_i$ ,  $X_i$ ,  $\xi_i$ , the first-order conditions for the optimal  $B_i$  are  $U_4 + U_5 = 0$ . If  $B_i$  equals either  $B_I$  or  $B_{N,i}$ , the first-order conditions fail. If  $B_i = B_p$ , then individual *i* can increase expected utility by increasing  $B_i$ .<sup>14</sup>

The optimal  $B_i$  is also increasing in  $B_{N,i}$ . A total differentiation of the first-order conditions with respect to  $B_i$  and  $B_{N,i}$  gets

(7) 
$$(U_{44} + U_{55} + 2U_{54})dB_i - U_{55}dB_{N,i} = 0$$
  
$$\frac{dB_i}{dB_{N,i}} = \frac{U_{55}}{U_{44} + U_{55} + 2U_{54}} > 0.$$

This result shows that  $B_{N,i}$  can be high enough that obesity is a rational and optimal choice.

If the consumer decides to purchase health insurance, then the first-order conditions for the optimal choice of  $B_i$  is  $U_4(\pi_i, c_{I,i}, X_i, B_i - B_I, B_i - B_{N,i}, \xi_i) + U_5(\pi_i, c_{I,i}, X_i, B_i - B_I, B_i - B_{N,i}, \xi_i) = 0$ , and if the consumer decides not to buy insurance, the first-order conditions are  $U_4(0, c_{N,i}, X_i, B_i - B_I, B_i - B_{N,i}, \xi_i) + U_5(0, c_{N,i}, X_i, B_i - B_I, B_i - B_{N,i}, \xi_i) = 0$ . Letting  $B_i^{t*}$  and  $B_i^{N*}$  be, respectively, the optimal choices for BMI for being insured and uninsured, the consumer chooses to be insured if

(8) 
$$U(\pi_{i}, c_{I,i}, X_{i}, B_{i}^{I^{*}} - B_{I}, B_{i}^{I^{*}} - B_{N,i}, \xi_{i}) > U(0, c_{N,i}, X_{i}, B_{i}^{N^{*}} - B_{I}, B_{i}^{N^{*}} - B_{N,i}, \xi_{i}).$$

Given the conditions in equation (6), we show in the first section of the appendix that  $B_i^{I^*} > B_i^{N^*}$ . Thus, insurance can generate ex ante moral hazard when it comes to BMI choices.<sup>15</sup>

In the second section of the appendix we show that there is also adverse selection, or equivalently, that an increase in  $B_{N,i}$  increases the propensity to purchase health insurance.

14. The second-order condition is  $U_{44} + U_{55} + 2U_{54} < 0$ .

15. There are two types of moral hazard, ex post and ex ante. Ex post moral hazard occurs from the ex post overconsumption of medical services because the consumer does not pay the full marginal costs. Ex ante moral hazard occurs because efforts to prevent diseases are non-contractible in an insurance policy or premiums can't adjust for BMI choices and consumers are not compensated for the effects that their efforts at prevention have on expected benefits. Additionally, they get a lower return on their preventive efforts because they are only paying a fraction of the full costs of getting ill. In this study, the effort is the disutility of nonsatiation when setting the BMI below the natural BMI. See Bradley (2005) or Bhattacharya and Sood (2006) on a fuller depiction of ex ante moral hazard and Pauly (1968) on ex post moral hazard.

This simple model predicts both ex ante moral hazard and adverse selection. The empirical section of this study will test the predictions of this simple micromodel. The intuition here is that  $B_{N,i}$  is private, asymmetric information that only the individual knows. The premium,  $\pi_i$ , cannot be risk adjusted for this private information. Since the optimal  $B_i^*$  choice monotonically increases with  $B_{N,i}$ , we can use  $B_i^*$  as an endogenous proxy when econometrically testing for adverse selection. The ex ante moral hazard occurs because the insured individual bears a smaller financial burden for her BMI decisions, and the BMI choice cannot be written into a health insurance contract.

In this framework, insurance choice, BMI choice, provider visits, and medical costs are influenced by variables  $B_{N,i}$  and  $\xi_i$  that are not observable to the econometrician. Simply modeling medical cost (or  $C_i$  in equation [2]) by using insurance and  $B_i$  as an exogenous regressors, and not accounting for the provider-visit decision, will lead to endogeneity bias. Obviously, we cannot estimate equation (2) directly because we cannot observe  $S_i$  When we substitute equation (1) to equation (2) and take logs, the estimating cost equation is

(9) 
$$\ln C_i = a + \alpha \ln(c_i) + X_i \beta_1 + (|B_i - B_i|)\beta_2 + \xi_i + \varepsilon_i.$$

The coefficient of interest is  $\beta_2$ . However, we cannot observe  $\xi_i$ . Yet, it influences both insurance and BMI choice. Suppose both  $C_i > 0$  and  $I_i = 1$ , then both conditions (4) and (8) hold where  $H(S_i(X_i, \xi_i), t_i, c_i) > 0$ , and  $U(\pi_{i,c}c_{I,i}, X_i, B_i^{I^*} - B_I, B_i^{I^*} - B_{N,i}, \xi_i) > U(0, c_{N,i}, X_i, B_i^{N^*} - B_I, B_i - B_{N,i}, \xi_i)$ . The right-side regressors of equation (9) are correlated with

(10) 
$$\lambda(\pi_i, c_i, t_i, X_i) = E(\xi_i \mid \{H(S_i(X_i, \xi_i), t_i, c_i) > 0\}$$
$$\bigcap \{U(\pi_i, c_{I,i}, X_i, B_i^{I^*} - B_I, B_i^{I^*} - B_{N,i}, \xi_i) > U(0, c_{N,i}, X_i, B_i^{N^*} - B_I, B_i - B_{N,i}, \xi_i)\}).$$

We rewrite equation (9) as:

(11)  

$$\ln C_{i} = a + \alpha \ln(c_{i}) + X_{i}\beta_{1}$$

$$+ (|B_{i} - B_{i}|)\beta_{2} + \lambda(\pi_{i}, c_{i}, t_{i}, X_{i})$$

$$+ \nu_{i} + \varepsilon_{i},$$

$$\xi_{i} = \lambda(\pi_{i}, c_{i}, t_{i}, X_{i}) + \nu_{i}.$$

Here equation (11) is a tobit model with two selection effects, the insurance decision and the provider insurance effects. Models such as these are rarely covered in the econometrics literature. Maddala (1983, 278–83) briefly covers models with multiple selectivity, and without proof provides the estimating procedure for extending the Heckit model for two-selection effects.

The microfoundations in this section lead me to a different estimation strategy than Cawley and Meyerhoefer (2012), who emphasize evidence that

genetic factors are the major determinant of weight. They do not model BMI determination as the result of decisions based on unobserved conditions. However, our micromodel predicts that ex post medical costs are a function of the simultaneous ex ante insurance and BMI decisions. The BMI decisions will affect costs both directly and through health insurance decisions. This is a feature that the Cawley and Meyerhoefer (2012) model misses. In our model, the natural BMI,  $B_{N,i}$  is a condition that could easily be influenced by genetic factors, but in the end, individual *i*'s BMI,  $B_i$ , is the result of a decision-making process. To correct for the endogeneity of BMI, we use a control variable approach where we estimate a reduced-form equation for  $B_i$ . To test the result,  $B_i^{I*} > B_i^{N*}$  or that insurance induces the increase in BMI, we estimate a structural form for  $B_i$  where private insurance is endogenous.

This study's biggest departure from Cawley and Meyerhoefer (2012) is that they use a two-part model where in the first part the provider-visit decision is estimated with a logit model, and in the second part the cost equation conditional on nonzero medical expenditures is estimated independently as a gamma regression with a log link. They do not mention how they treat insurance choice, and they do not even report insurance status as a summary statistic. Their methods will only provide consistent estimates as long as the multiple-selection effects,  $\lambda(\pi_i, c_i, t_i, X_i)$  in equation (11), are zero everywhere. We find that the multiple-selection effects are statistically significant.<sup>16</sup>

# 7.3 Data and Estimating Equations

#### 7.3.1 Data

The Medical Expenditure Panel Survey (MEPS) is a stratified random sample of households in the United States in which each household remains in the sample for two years. Each year new households are sampled, and for a given year a household was either in the sample in the previous year or it was not. The survey collects for each household individual her medical expenditures, her diagnosed diseases, her perceived health status, her insurance status, her employment, and her demographic variables. While each household is interviewed five times, medical expenditures are only reported annually. This survey also surveys the medical providers and pharmacies used by the households in order to obtain more accurate expenditure data.

The MEPS household file has each individual as a unique observation and lists the total annual medical expenditure along with the economic, demographic, and BMI information. The conditions file has a diagnosed

<sup>16.</sup> There is a debate between the relative merits of the two-part model and the Heckit model. Dow and Norton (2003) argue that the Heckit model is often misused and *t*-tests for the null hypothesis,  $\lambda(\pi_i, c_i, t_i, X_i) = 0$ , perform poorly.

condition as the unique observation, and a new record is created with each newly reported treated disease. The event files has a separate record for each office, outpatient, emergency room, and hospital visit. There is also a separate record for each pharmaceutical refill.<sup>17</sup>

Since 2002, MEPS has collected individual BMIs. Thus, the sample in this study starts in 2002 and ends in the last year available, 2010.

Figure 7.1 shows how the obesity rate has climbed from 2002 to 2010. Figure 7.2 compares the kernel densities for BMI for 2002 and 2010. The 2010 distribution is "flatter" and mass migrated from the 21 to 26 range in 2002 to the 30 to 45 range in 2010. Figure 7.3 compares the kernel densities for nominal per-person medical expenditures. Both the 2002 and 2010 distributions are skewed to the left. Again, the 2010 distribution is flatter and there are larger outliers. Figure 7.4 compares individual medical expenditures in 2002 dollars.<sup>18</sup> While there is a slight increase in the average, the densities have not changed greatly.

Table 7.1 lists selected summary statistics for the beginning year and ending year of this study.<sup>19</sup> Of note, the national obesity rate has climbed from 17.5 percent in 2002 to 21.5 percent in 2010. The fraction of individuals with no medical visits and cost ( $C_i = 0$ ) rose from 14.8 percent in 2002 to 15.4

19. The standard errors of the mean are in parentheses. Since MEPS is a stratified random sample, variance estimation needs to account for the stratification. In this study, we use the Taylor Series (linearization) method.

<sup>17.</sup> Since MEPS is a stratified sample, consistent variance estimation requires accounting for the clustering of the primary-sampling units and strata.

<sup>18.</sup> To get real medical expenditures, we deflate by the medical CPI so that all medical expenditures can be expressed in 2002 dollars.

Fig. 7.2 A comparison of BMI densities between 2002 and 2010 *Source:* Medical Expenditures Panel Survey 2002 and 2010.

**Fig. 7.3 Per-person nominal medical expenditure densities between 2002 and 2010** *Source:* Medical Expenditures Panel Survey 2002 and 2010.

percent in 2010. The MEPS attempts to record actual household expenditures. If an individual visits, say, an emergency room, and this visit is not reimbursed, then the event file will record a zero expenditure for this visit. In 2002, 14.7 percent of all individuals had at least one fully unreimbursed visit and this rose to 15.3 percent in 2010. This can present challenges when attempting to measure the effect of obesity on costs. Even though a visit goes unreimbursed, this does not mean that the cost of the visit is zero. This table also shows that in 2010 a smaller fraction of the population had access to a primary care physician and were covered by private health insurance.

| Table 7.1 | (continued) |
|-----------|-------------|
|-----------|-------------|

Nominal medical spending per capita increases from \$2,813 to \$4,094, while medical spending in 2002 dollars rises only to \$3,010 in 2010.

We impute a cost for unreimbursed visits by a using an average with a shock for reimbursed expenditures. While there are controversies behind this approach, we do it to get an alternative per capita cost. Table 7.1 shows that the imputation in 2002 adds \$600 to the per capita costs.

# 7.3.2 Estimating Equations

# Ex Ante Period

To simplify exposition, we change notation slightly in this subsection. Now X represents all the observable right-side covariates, and  $\xi$  represents all unobservables, including  $B_{Ni}$  and  $t_i$ . Different models will have different right-side covariates and there is an additional subscript to distinguish the different covariates among the different models.

We model the ex ante period first where BMI and insurance choices are made. We want to verify that there is both ex ante moral hazard and adverse selection as the simple micromodel predicts.

We start with the reduced-form BMI  $(B_i)$  equation. We first need to control for the effects of responding to the weight question, as not all MEPS respondents responded. We estimate a probit model for responding to the weight question in MEPS. Let  $X_{i,R}$  be the observable characteristics that govern the response to the weight question in MEPS. The individual responds if

$$(12) X_{i,R}\beta_R + u_{i,R} > 0$$

where  $u_{i,R} \sim N(0, 1)$  and contains the effects of  $\xi_i$ . (From here on, all residuals, u, contain the effects of  $\xi_i$ ; so for equation [12]  $u_{i,R} = \gamma_R \xi_i + v_{R,i}$  where  $v_{R,i}$ is an unobservable residual that effects the response decision, but not the ex post variable  $S_i$ .) Let  $\hat{\beta}_R$  be the parameter estimate. We can next estimate the reduced-form equation for BMI  $(B_i)$  as

(13) 
$$B_i = X_{i,B}\beta_B + \lambda(X_{i,R}\beta_R) + u_{i,B}$$

where  $u_{i,B}$  is a mean zero residual and  $X_{i,B}$  are exogenous covariates;  $\lambda(X_{i,R}\hat{\beta}_R)$ is the inverse Mills ratio using the parameter estimate from equation (12). The estimated residual,  $\hat{u}_{i,B}$ , is the control variable that corrects for the endogeneity of  $B_i$  in the other models.

We estimate a structural health insurance choice model using the control variable to correct for the endogeneity of BMI choice. Let  $X_{i,i}$  represent both the observable endogenous and exogenous covariate influencing insurance choice. Then

$$I_i = 1 \implies X_{i,I}\beta_I + u_{i,I} > 0$$
$$I_i = 0 \implies X_{i,I}\beta_I + u_{i,I} \le 0.$$

In this model the coefficient for BMI is the coefficient of interest. If it is positive and significant, this gives evidence that there is adverse selection.

Next, we add private insurance status to  $X_{iB}$  in equation (12) and account for its endogeneity. When we reestimate this BMI model, interest is on the private insurance coefficient. The coefficient of interest is the private insurance effect. If it is positive and significant, then there is evidence of ex ante moral hazard.

#### Ex Post Period

In the expost period, the individual decides whether or not to visit a provider, and if there is a visit then medical expenditures are set. As discussed in the section in the micromodel, the BMI, insurance, and provider visit decisions are a function of unobserved individual characteristics,  $\xi_i$ . The residuals,  $u_{i,B}$  and  $u_{i,I}$ , from the ex ante models are functions of  $\xi_i$  as they were in the ex ante subsection.

The decision to visit a medical provider and the resulting medical expenditure from a visit are also functions of  $\xi_i$ . Therefore, BMI is an endogenous right-side regressor where a control variable is used to correct for its endogeneity. The ex ante choice of insurance status and the ex post decision to visit a provider generate a multiselection effect. The individual decision to visit a provider is specified as

(14) 
$$C_i > 0 \Rightarrow X_i^C \beta_C + u_{i,C} > 0$$
$$C_i = 0 \Rightarrow X_i^C \beta_C + u_{i,C} \le 0.$$

Finally, if  $C_i > 0$ , then medical expenditures estimated as a gamma regression with mean  $\mu_i$  and a log link function

$$\ln\mu_i = X_i^{C>0}\beta_{C>0}$$

+ multiple selection effects.

Notice that  $X_i^C \beta_C$  in the visit choice equation (14) is not the same as  $X_i^{C>0} \beta_{C>0}$  in the medical cost equation since it is the individual that is solely involved in the visit decision, but the physician is involved in the setting of medical expenditures. In the third section of the appendix, we detail how we first estimate the multivariate probit for the joint event of being insured and visiting a provider or

$$\Pr(\{X_i^C \beta_C + u_{i,C} > 0\} \cap \{X_i^I \beta_I + u_{i,I} > 0\}),\$$

and then use this estimation to compute the multiple-selection effects.

#### 7.4 Results

#### 7.4.1 Models for the Ex Ante Period

Table 7.2 lists the parameter estimates of the probit model in equation (12) for responding to the MEPS weight questionnaire. Males are more likely to respond than females. Response improves with education. Most of the year dummies do not produce significant results. Unemployed individuals are less likely to respond. As one ages, one is less likely to respond.

Table 7.3 lists the results for the reduced-form BMI equation in (13). We used the Producer Price Index (PPI) for corn syrup divided by the all items Consumer Price Index (CPI) as a proxy for the relative price for the food. Corn syrup is an intermediate product for foods considered the major culprit behind obesity. The parameter estimate is negative but not significant. Income is excluded for endogeneity reasons, but we include a regressor label

| Variable                              | Estimate |

Control equation for BMI

\*\*Significant at the 1 percent level.

\*Significant at the 5 percent level.

Table 7.3

"number of high occupations." This is the total number of people in the individual's household who are either in a professional, technical, or government occupation. It proxies one's ability to access resources that can help control weight such as gyms and better food. We exclude the individual's own income because of possible income discrimination against obese individuals. We include spouse's income, and set to 0 for single individuals. While the coefficient on the number of high occupations is significantly negative, the coefficient for the spouse's income is positive and significant although it is small in magnitude. The most interesting result is that if one does a simple Heckit, the coefficient on the inverse Mills ratio is negative. We then add the square of the inverse Mills ratio. The parameter estimate for the squared term is negative, while it is positive for the regular inverse Mills ratio. It seems that the BMIs where the sum of these two terms peak is in the 26 to 28 BMI range. This is the range where it is perhaps most possible to hide one's true weight.

Table 7.4 shows the parameter estimates for the ex ante insurance choice in equation (14). The coefficient of interests is for the BMI  $(B_i)$  and it is significantly positive. This leads to the conclusion that there is adverse selection with BMI. Individuals with higher BMI are more likely to purchase insurance. The other results are not surprising. Young men have a lower propensity to purchase insurance, where as individuals with children who do not benefit from the State Children's Health Insurance Program (SCHIP) where both spouses work in technical, professional, or government occupations have a much higher propensity to purchase insurance.

Table 7.5 lists the parameter estimates from a structural BMI equation where private insurance is treated as an endogenous variable. The coefficient of interest is the dummy variable for being privately insured. This provides evidence of ex ante moral hazard.

In the ex ante period, both insurance status and BMI are determined. If the individual purchases insurance, the financial consequences of illness are less severe, and the policyholder is not compensated by the plan for the savings generated by suffering additional disutility to get the BMI nearer to an ideal level. This is ex ante moral hazard.

Likewise, employer-sponsored insurance premiums do not seem to be risk adjusted for increases in BMI. As BMI increases, so does the risk of severe diseases. This increases the expected utility of holding health insurance. This is adverse selection.

# 7.4.2 Models for the Ex Post Period

The goal is to estimate a cost equation. Yet, the choice to visit a provider in the ex post period and the ex ante choice of insurance status are statistically dependent decisions (because of  $\xi_i$ ), and will influence medical spending if and when the individual decides to visit a provider.

We estimate a multiple-selection model where the estimation methods is detailed in the third section of the appendix. In this method, we first estimate

| Intercept         -2.46112**           (0.1131)         Age           -0.00009           (0.0016)           EDUCYR         0.11093**           0.00488           BMI         0.00510**           (0.0012)         Male           -0.39402**           (0.0013)           Male         -0.39402**           (0.0013)           Age * male         0.00464**           (0.0018)           Household size         0.21084**           (0.0375)           Individual income         0.00002**           (0.0375)           Individual income         0.00001**           (0.0319)         Black         0.1209*           (0.0401)         Perceived poor health         -0.23748**           (0.0300)         Perceived poor health         -0.23748**           (0.0401)         Perceived excellent health         0.06659*           (0.0286)         Number of children         0.0236)           Number of children         0.02947**           (0.0273)         Dummy for 2002         0.37017**           (0.0439)         Dummy for 2003         0.29947**           (0.04489)         Dummy for 2005         0.  | Variable                   | Estimate   |

 Table 7.5
 BMI choice with insurance as endogenous

\*\*Significant at the 1 percent level.

\*Significant at the 5 percent level.

a bivariate normal probit for insurance choice ( $I_i = 1$  or 0) and for provider choice ( $C_i > 0$  or  $C_i = 0$ ). The results of this model are detailed in table 7.6. The income variables have been scaled where they are divided by \$100,000. The estimated parameters have signs that are expected except for the "poor perceived health" coefficient, which is negative in the insurance-choice equation. Perhaps, most who have poor perceived health find that medical treatments are not effective at mitigating their illness, and this gives them less propensity to insure. The coefficient  $\rho$  that measures the statistical dependence between the two decisions is positive and significant.

It should be noted that the corner solution tobit effects for  $(C_i > 0)$  are not as simple as the standard tobit model (type 1) as depicted in section 10.2 of Amemiya (1985). It better conforms to the type 2 definition as defined

| Insurance propensity       | Estimate      | Propensity to visit provider | Estimate |

in section 10.7 of Amemiya (1985), where the covariates of the selection effect of choosing to visit can be different from the covariates in the medical expenditure equation. The visiting decision is made solely by the individual, whereas the physician has final authority over the medical expenditure decision.

The parameter estimates for the gamma medical expenditure regression with a log link function are listed in table 7.7. We estimated one regression without imputing the zero costs for unreimbursed payment and another with the imputed costs. All the coefficients have the expected sign except for the visit selection effect,  $E_{i2}$  as defined in equation (A.7) in the third section of the appendix. The result here says that those with a very low propensity to visit a provider do end up generating higher costs when they do see a provider. In our micromodel in equation (4), the individual's underlying illness severity,  $S_i$  is not the only variable influencing the decision to visit the provider. There is also the nonmonetary cost variable,  $t_i$  (as depicted in equation [4]), that is randomly distributed throughout the population. This variable will have a large absolute value if individual *i* has a phobia against visiting providers. Suppose that individuals *i* and *j* have the same observable covariates, X, but if *i* has a phobia against visiting physicians but *i* does not, then  $t_i > t_i$ . This implies that threshold sickness level of *i* to visit a provider is greater than j's threshold level. Since they have the same observable variables, it must be that when *i* does visit a provider, the expected value of  $\xi_i$  is greater than the expected value of  $\xi_i$ . This implies that given that both *i* and *i* have decided to visit a provider, the expected value of *i*'s expenditure will be greater than i's expected expenditure. For example, suppose both individuals have colon cancer. Individual j goes to the provider when this cancer is in its early stages, and individual *i* waits until the cancer is extreme and has spread throughout his body.

The other coefficients have their expected signs. The insurance effect is positive and significant as expected. The BMI coefficient is significant and positive.

# 7.4.3 Simulations

We run three separate simulations. The first one estimates the cost of obesity on a per-person basis. This is the same estimation as the \$2,741 estimate made by Cawley and Meyerhoefer (2012). The second one estimates the effect of a 10 percent BMI reduction for all obese persons. The last estimates the obesity elasticity of cost.

Impact of obesity on medical cost

Table 7.8

| Cost of obesity   | Estimate<br>(\$) |
|---|------------------|
| Average direct cost of obesity                              | 430.52           |
| Cost from additional propensity to insure                   | 3.83             |
| Cost reduction from increase propensity to visit provider   | -4.02            |
| Cumulative effects  | 430.33           |
|   | Estimate         |
| Average effect of a 10 percent reduction in BMI             | (\$)             |
| Average direct effect                                       | -45.44           |
| Effect from reduced propensity to insure                    | -0.63            |
| Effect from reduced propensity to visit provider            | 0.79             |
| Cumulative effects  | -45.28           |
|   | Estimate         |
| Percent reduction in cost from a 1 percent reduction in BMI | (%)              |
| Direct  | 0.0115           |
| Effect from insurance propensity                            | 0.0002           |
| Effect from visiting propensity                             | -0.0003          |
| Cumulative effects  | 0.0115           |

The results of the simulation are listed in table 7.8; our counterpart estimate to Cawley and Meyerhoefer (2012) is \$430. We break down the components of this effect into the effects coming from insurance change and change-in-visit propensity, as well as the direct effect. Notice that the increased-visiting propensity actually reduces costs by \$4. Our result represents 14 percent of real per-person expenditures in 2010. My results are 84 percent lower than Cawley and Meyerhoefer (2012).

Obesity has always been with us and it will not go away. Therefore, we do not believe that the correct question is the cost of obesity. It might be more instructive to determine the impact of an exogenous 10 percent in BMI for all obese persons. Table 7.8 reports a \$45 reduction if all obese persons reduce their BMI by 10 percent. There are many reasons that our results might differ from the Cawley and Meyerhoefer (2012) results. Our estimation uses all adults who are not eligible for public insurance, while they use only adults with biological children. Our estimation methods are vastly different. We use a control variable method to account for the endogeneity of BMI in a cost estimation; they instrument with the BMI of biological children. We also model and estimate how individuals make their BMI decisions and this influences our parameter estimates, but do not influence Cawley and Meyerhoefer's (2012) estimates. We also account for the endogeneity of insurance.

Finally, we find the percent reduction in costs for every 1 percent decrease in BMI for obese persons. Here the elasticity is only .0115 percent.

High BMI does increase costs, but a policy that is successful in reducing BMI will not generate the cost savings that were previously thought.

#### 7.5 Conclusions

While we do find that obesity does have a positive impact on health care costs, its magnitude is lower than that of Thorpe, Florence, and Joski (2004), and especially Cawley and Meyerhoefer (2012). It conforms more closely to results from Baker and Duchnovny (2010). They found that "if the distribution of adults by weight between 1987 and 2007 had changed only to reflect demographic changes, then health care spending per adult in 2007 would have been roughly 3 percent below the actual 2007 amount." Unlike Cawley and Meyerhoefer (2012), we do not limit our attention to adults with biological children.

Nonetheless, obesity is a national problem and it continues to increase. While we have found that moral hazard plays a role in setting BMI choices, and likewise BMI is a consideration in health insurance choices, we have not been able to answer the questions, "Why is obesity increasing when we know its adverse health effects?" and "Why haven't past private and public interventions worked?" The answers to these questions, perhaps, require the coordinated research of many disciplines—biology, epidemiology, statistics, and maybe even economics. Yet, our micromodel might provide an initial clue. Perhaps current intervention programs underestimate the marginal disutility that obese individuals face when reducing an additional BMI. People enter these interventions with a false notion of the required effort, and this leads most to fail.

One major problem of modeling and estimating health care costs is that the observable covariates such as age, gender, race, and so forth, explain very little of the variation of health care costs. This gives evidence that the unobserved characteristics that we denote as  $\xi_i$  in this study play a larger role in cost determination than the observable characteristics.

We have findings that are unrelated to obesity, but they are important. A higher propensity to visit a provider reduces expected health costs because diseases can be treated at an earlier stage. Important in this decision to visit a provider is the access to a primary provider. The MEPS survey shows that from 2002 to 2010 the percentage of individuals with a primary provider has dropped from 79.7 percent to 78.0 percent. This trend could have negative effects on both future costs and health outcomes.

# Appendix

Proof  $B_i^{I^*} > B_i^{N^*}$ 

This is the proof that  $B_i^{I^*} > B_i^{N^*}$ . Differentiating  $U_4(0, c_{N,i}, X_i, B_i - B_I, B_i - B_{N,i}, \xi_i) + U_5(0, c_{N,i}, X_i, B_i - B_I, B_i - B_{N,i}, \xi_i) = 0$  with respect to both  $B_i$  and  $c_i$  gets

$$U_{42}dc_i + (U_{44} + U_{55} + 2U_{54})dB_i = 0.$$

The second-order condition of the optimization for  $B_i$  is  $U_{44} + U_{55} + 2U_{54} < 0$ . Thus

$$\frac{dB_i}{dc_i} = -\frac{U_{42}}{U_{44} + U_{55} + 2U_{54}} < 0.$$

Since  $c_{Li} < c_{N,i}$ , the result holds.

Proof of Increases in  $B_{N,i}$  Increases Propensity to Insure

The individual insures if

$$U^{I} = U(\pi_{i}, c_{I,i}, X_{i}, B_{i}^{I^{*}} - B_{I}, B_{i}^{I^{*}} - B_{N,i}, \xi_{i}) >$$

$$U(0, c_{N,i}, X_i, B_i^{N^*} - B_I, B_i - B_{N,i}, \xi_i) = U^N.$$

An increase in  $B_{N,i}$  will increase the propensity to insure if

$$U_{4}^{I} \frac{dB_{i}^{I^{*}}}{dB_{N,i}} + U_{5}^{I} \left(\frac{dB_{i}^{I^{*}}}{dB_{N,i}} - 1\right) - U_{4}^{N} \frac{dB_{i}^{N^{*}}}{dB_{N,i}} + U_{5}^{N} \left(\frac{dB_{i}^{N^{*}}}{dB_{N,i}} - 1\right) > 0.$$

From the Envelope Theorem,

$$U_4^I \frac{dB_i^{**}}{dB_{N,i}} + U_5^I \frac{dB_i^{**}}{dB_{N,i}} = U_4^N \frac{dB_i^{N*}}{dB_{N,i}} + U_5^N \frac{dB_i^{N*}}{dB_{N,i}} = 0.$$

Thus, I need only show that  $U_5^N > U_5^I$ . This result holds because from the first appendix section,  $B_i^{I^*} > B_i^{N^*}$ .

Derivation of Multiselection Effects

Let  $X_i^I$  and  $X_i^C$  be, respectively, the observed variables that influence the decision to insure and the decision to visit a medical provider. The individual will insure if

(A.1) 
$$X_i^I \beta_I + u_{i,I} > 0,$$

and will visit a provider if

(A.2) 
$$X_i^C \beta_C + u_{i,C} > 0.$$

You are reading copyrighted material published by University of Chicago Press. Unauthorized posting, copying, or distributing of this work except as permitted under U.S. copyright law is illegal and injures the author and publisher.

If the individual visits a provider, then medical expenditures  $C_i$  has a gamma distribution with mean  $\mu_i$ . I posit a log link function where

(A.3) 
$$\ln \mu_i = X_i^{C>0}\beta_{C>0} + E(\xi_i | \{X_i^C\beta_C + u_{i,C} > 0\} \cap \{X_i^I\beta_I + u_{i,I} > 0\}$$
  
for insured patients, and for uninsured patients

(A.4)  $\ln \mu_i = X_i^{C>0} \beta_{C>0} + E(\xi_i | \{X_i^C \beta_C + u_{i,C} > 0\} \cap \{X_i^I \beta_I + u_{i,I} \le 0\}.$ I then posit

(A.5) 
$$\begin{bmatrix} u_{i,I} \\ u_{i,C} \\ \xi_i \end{bmatrix} \sim N(0, \Sigma).$$

Let  $\Sigma_{i,j}$  be the (i, j) element of  $\Sigma$ ;  $\Sigma_{1,1} = \Sigma_{2,2} = 1$  and  $\Sigma_{1,2} = \rho$ . Then, from Manjunath and Stephan (2012)

(A.6) 
$$E(\xi_i \mid \{a_1 < u_{i,I} < b_1\} \cap \{a_2 < u_{i,C} < b_2\}) = \sum_{1,3} E_{1,i} + \sum_{2,3} E_{2,i}$$

and

(A.7) 
$$E_{1,i} = E(u_{i,I} \mid \{a_1 < u_{i,I} < b_1\} \cap \{a_2 < u_{i,C} < b_2\})$$

$$E_{2,i} = E(u_{i,C} \mid \{a_1 < u_{i,I} < b_1\} \cap \{a_2 < u_{i,C} < b_2\}).$$

More specifically, let  $c = 1 / \sqrt{1 - \rho^2}$ 

(A.8) 
$$E(u_{i,I} | \{a_1 < u_{i,I} < b_1\} \cap \{a_2 < u_{i,C} < b_2\})$$
  
=  $\phi(a_1)[\Phi((b_2 - \rho a_1)c) - \Phi((a_2 - \rho a_1)c)]$   
-  $\phi(b_1)[\Phi((b_2 - \rho b_1)c) - \Phi((a_2 - \rho b_1)c)]$   
+  $\rho\phi(a_2)[\Phi((b_1 - \rho a_2)c) - \Phi((a_1 - \rho a_2)c)]$   
-  $\rho\phi(b_2)[\Phi((b_1 - \rho b_2)c) - \Phi((a_1 - \rho b_2)c)].$ 

Likewise, let 
$$p = \Pr\{a_1 < u_{i,I} < b_1\} \cap \{a_2 < u_{i,C} < b_2\}$$
, then  
(A.9)  $pE(u_{i,C} \mid \{a_1 < u_{i,I} < b_1\} \cap \{a_2 < u_{i,C} < b_2\})$   
 $= \phi(a_2)[\Phi((b_1 - \rho a_2)c) - \Phi((a_1 - \rho a_2)c)]$   
 $- \phi(b_2)[\Phi((b_1 - \rho b_2)c) - \Phi((a_1 - \rho b_2)c)]$   
 $+ \rho\phi(a_1)[\Phi((b_2 - \rho a_1)c) - \Phi((a_2 - \rho a_1)c)]$   
 $- \rho\phi(b_1)[\Phi((b_2 - \rho b_1)c) - \Phi((a_2 - \rho b_1)c)].$ 

To estimate the selection effects,  $\sum_{1,3}E_{1,i} + \sum_{2,3}E_{2,i}$ , I start with a bivariate probit estimation of  $I_i = 1$  and  $C_i > 0$ , or

(A.10) 
$$\Pr(X_i^I \beta_I + u_{i,I} > 0, X_i^C \beta_C + u_{i,C} > 0) = \Pr(-u_{i,I} < X_i^I \beta_I, -u_{i,C} < X_i^I \beta_I)$$
  
=  $\Phi(X_i^I \beta_I, X_i^C \beta_C, \rho)$ 

where  $\Phi(.,.,.)$  is a standard bivariate normal distribution. Let  $\hat{\beta}_{I}, \hat{\beta}_{C}, \hat{\rho}$  be the parameter estimates from this bivariate probit estimation. Then if  $I_{i} = 0$  and  $C_{i} = 0$ , I compute equations (A.9) and (A.10) by setting  $a_{1} = -\infty, b_{1} = -X_{i}^{I}\hat{\beta}_{I}, a_{2} = -\infty, \beta_{2} = -X_{i}^{C}\hat{\beta}_{C}, \text{ and } \rho = \hat{\rho}$ . Likewise if  $I_{i} = 0$ and  $C_{i} > 0$ , then  $X_{i}^{I}\beta_{I} + u_{i,I} \leq 0$  or  $u_{i,I} \leq -X_{i}^{I}\beta_{I}$  and  $X_{i}^{C}\beta_{C} > -u_{i,C}$ . I compute equations (A.9) and (A.10) by setting  $a_{1} = -\infty, b_{1} = -X_{i}^{I}\hat{\beta}_{I}, a_{2} = -\infty,$  $\beta_{2} = X_{i}^{C}\hat{\beta}_{C}, \text{ and } \rho = -\hat{\rho}$ . I do similar calculations for ( $I_{i} = 1$  and  $C_{i} = 0$ ) and ( $I_{i} = 1$  and  $C_{i} > 0$ ).

The parameters  $\Sigma_{1,3}$  and  $\Sigma_{2,3}$  are estimated as coefficients in the gamma regression of cost equation. Apparently, there is a negative coefficient for  $\Sigma_{2,3}$ . This is evidence that individuals with a high unobserved propensity not to see a provider (i.e., a highly negative  $u_{i,C}$ ) will generate higher medical costs if they do see a provider because they have usually waited too long to see a provider and are sicker than they would have been if they had seen a provider sooner.
