ABSTRACT

Do bankrupt firms impose negative externalities on their non-bankrupt competitors? We propose and analyze a collateral channel in which a firm's bankruptcy reduces collateral values of other industry participants, thereby increasing the cost of external debt finance industry wide. To identify this collateral channel, we use a novel dataset of secured debt tranches issued by U.S. airlines which includes a detailed description of the underlying assets serving as collateral. Our estimates suggest that industry bankruptcies have a sizeable impact on the cost of debt financing of other industry participants. We discuss how the collateral channel may lead to contagion effects which amplify the business cycle during industry downturns.

Introduction

Do bankrupt firms affect their solvent non-bankrupt competitors? While there is a large body of research studying the consequences of bankruptcy reorganizations and liquidations for those firms that actually file for court protection (e.g. Asquith et al. (1994), Hotchkiss (1995), and Strömberg (2000)), little is known about the externalities that bankrupt firms impose on other firms operating in the same industry. Any such externalities would be of particular concern, as they may give rise to self reinforcing feedback loops that amplify the business cycle during industry downturns. Indeed, the potential for contagion effects has been of particular concern in the ongoing financial panic of 2007-2009 where insolvent bank liquidations and asset sell offs impose 'fire-sale' externalities on the economy at large (see e.g. Kashyap et al. (2008)).

In this paper we identify one channel in which bankrupt firms, through their impact on collateral values, impose negative externalities on non-bankrupt competitors. We use the term 'collateral channel' to describe this effect. According to the collateral channel, a firm's bankruptcy reduces collateral values of other industry participants, particularly when the market for assets is relatively illiquid. Since collateral plays an important role in raising debt finance, this reduction in collateral values will increase the cost and reduce the availability of external finance across the entire industry.

Theory provides two interrelated reasons for the prediction that bankruptcy of industry participants lowers collateral values of other industry participants. First, a firm's bankruptcy and the resultant increased likelihood of asset sales will place downward pressure on the value of similar assets, particularly when there are frictions in this secondary market. For example, in an illiquid market, bankruptcy induced sales of assets will create a disparity of supply over demand, causing asset prices to decline, at least temporarily. In the context of real estate markets, whose collapse was of crucial importance in instigating and magnifying the crisis, Campbell et al. (2009) provide evidence of spillover effects in which house foreclosures reduce the price of other houses located in the same area.

The second reason that bankruptcies will tend to reduce collateral values is their impact on the demand for assets. When a firm is in financial distress, its demand for industry assets will likely diminish, as the firm does not have, and cannot easily raise, the funding which would be required to purchase industry assets (Shleifer and Vishny, (1992), Kiyotaki and Moore, (1997)). Thus, bankruptcies and financial distress reduce demand for industry assets, again placing downward pressure on the value of collateral. Reductions in demand for assets driven by bankruptcies and financial distress are currently evident in the difficulties the FDIC is encountering in selling failed banks. These difficulties have arisen because traditional buyers of failed banks – namely, other banks – are financially weak.[1]

Thus, both due to increased supply and reduced demand for industry assets, the collateral channel implies that bankruptcies increase the likelihood of asset fire sales, reducing collateral values industry wide. This weakens the balance sheet of non-bankrupt firms, thereby raising their cost of debt capital.

Empirically, a number of important outcomes have been shown to be sensitive to the announcement of bankruptcy of industry competitors. For example, Lang and Stulz (1992) show that when a firm declares bankruptcy, on average, competitor firm stock prices react negatively. Likewise, Hertzel and Officer (2008) and Jorion and Zhang (2007) examine the effect of bankruptcy on competitors' loan yields and CDS spreads. However, identifying a causal link from the financial distress or bankruptcy filings of some players in an industry to their solvent non-bankrupt competitors is difficult since bankruptcy filings and financial distress are potentially correlated with the state of the industry. Financial distress and bankruptcy filings themselves thus convey industry specific information, explaining, for example, negative industry wide stock price reactions and loan pricing effects. The question, therefore, remains: do bankrupt firms affect their competitors in a causal manner or do the observed adverse effects merely reflect changes in the economic environment faced by the industry at large?

Using a novel dataset of secured debt tranches issued by U.S. airlines, we provide empirical support for the collateral channel. Airlines in the U.S. issue tranches of secured debt known as Equipment Trust Certificates (ETCs), Enhanced Equipment Trust Securities (EETCs), and Pass Through Certificates (PTCs). We construct a sample of aircraft tranche issues and then obtain the serial number of all aircraft that were pledged as collateral. For each of the debt tranches in our sample we can identify precisely its underlying collateral. We then identify the 'collateral channel' off of both the time-series variation of bankruptcy filings by airlines, and the cross-sectional variation in the overlap between the aircraft types in the collateral of a specific debt tranche and the aircraft types operated by bankrupt airlines. The richness of our data – which includes detailed

[1] Indeed, to partially solve this problem, the FDIC is looking outside the traditional market, at private equity funds, to infuse fresh capital into the banking system and purchase failed financial institutions. See "New Rules Restrict Bank Sales, New York Times, August 26th, 2009.

information on tranches' underlying collateral and airlines' fleets – combined with the fairly large number of airline bankruptcies in our sample period, allows us to identify strategic externalities that are likely driven by a collateral channel rather than by an industry shock to the economic environment.

At heart, our identification strategy relies on analyzing the differential impact of an airline's bankruptcy on the credit spread of tranches which are secured by aircraft of different model types. According to the collateral channel hypothesis, tranches whose underlying collateral are of model types which have a large amount of overlap with the fleet of the bankrupt airline, should exhibit larger price declines than tranches whose collateral has only little overlap with the bankrupt airline's fleet.

For each tranche in our sample we construct two measures of bankruptcy induced collateral shocks. The first measure tracks the evolution over time of the number of airlines in bankruptcy operating aircraft of the same model types as those serving as collateral for the tranche. Since airlines tend to acquire aircraft of the same model types which they already operate, an increase in the first measure is associated with a reduction in the number of potential buyers of the underlying tranche collateral. The second measure of collateral shocks tracks the number of aircraft operated by bankrupt airlines of the same model type as those serving as tranche collateral. An increase in this second measure is associated with a greater supply of aircraft on the market similar to those serving as tranche collateral. Increases in either of these two measures, therefore, tend to decrease the value of tranche collateral and hence increase credit spreads.

Using both measures, we find that bankruptcy-induced collateral shocks are indeed associated with lower tranche spreads. For example, our univariate tests show that the mean spread of tranches with no potential buyers in bankruptcy is 208 basis points, while the mean spread of tranches with at least one potential buyer in bankruptcy is 339 basis points. Moreover, our regression analysis shows that the results are robust to a battery of airline and tranche controls, as well as airline, tranche and year fixed-effects.

We continue by showing that the effect of bankruptcy-induced collateral shocks on credit spreads is higher for less-senior tranches and tranches with higher loan-to-value. Further, we find that credit spreads of less profitable airlines display higher sensitivity to collateral shocks. Finally, using a host of robustness tests and analysis we show that our results are not driven by underlying industry conditions, or by other forms of potential contagion unrelated to the collateral channel.

The rest of the paper is organized as follows. Section 1 provides the theoretical framework for the analysis and explains our identification methodology. Section 2 provides the institutional details on the market for Equipment Trust Certificates and Enhanced Equipment Trust Certificates. Section 3 describes our data and the empirical measures. Section 4 presents the empirical analysis of the relation between bankruptcy-induced collateral shocks and credit spreads. Section 5 concludes.

1. Theory and Identification Strategy

Bankrupt firms may inflict indirect costs of financial distress on their non-bankrupt competitors, for example, by deterring customers and suppliers from dealing with firms in the same industry. However, the fact that non-bankrupt firms within the industry exhibit contemporaneous negative reactions might merely reflect a deteriorating economic environment. Lang and Stulz (1992) were the first to point to the empirical problem in identifying a causal contagious effect of bankruptcy. They write:

> *An oft-repeated concern is that bankruptcy is contagious within an industry. The common view is that one firm's bankruptcy makes customers and suppliers wary of the other firms in the same industry irrespective of their economic health and hence makes them worse off. An alternative, more benign, view of contagion is that the bankruptcy announcement reveals negative information about the components of cash flows that are common to all firms in the industry and, consequently, decreases the market's expectation of the profitability of the industry's firms. From an empirical perspective, it is difficult to distinguish between these two views of contagion, but they have strongly different implication for public policy. If contagion is only an information effect, it has no social costs.*

Several papers study intra-industry contagion effects of bankruptcy. Bernanke (1983) finds contagion effects during the great depression, while Warner (1977) finds no contagion in the railroad industry during the early 20th century. Lang and Stulz (1992) investigate the effect of bankruptcy announcements on equity values on the bankrupt firm's competitors. They find that bankruptcy announcements decrease the value of competitors in highly levered industries, while the effect is positive in highly concentrated industries with low leverage, suggesting that in these industries competitors benefit from the financial difficulties of bankrupt firms. Hertzel and Officer (2008) find that spreads on corporate loans are higher when the loan originates or is renegotiated during times in which industry rivals file for bankruptcy. Similar to Lang and Stulz (1992), they find that contagion in loan spreads is mitigated in concentrated industries. Likewise, Jorion and Zhang (2007) find evidence that is consistent with the contagion effect of bankruptcy using credit default swaps data.[2]

While making important contributions and advancing the knowledge about the empirical regularities in the data, none of these papers identify the direction of the causality from bankruptcy to industry contagion. Is bankruptcy contagious or benign? Moreover, the evidence in these paper does not pin down the mechanism through which bankruptcy affect competitors.

In this paper, we identify one channel, which we call the 'collateral channel', through which bankrupt firms impose negative externalities on their non-bankrupt competitors. In this collateral channel, a bankruptcy of an industry participant serves to lower the value of similar collateral industry wide. This occurs for two reasons. First, a firm's bankruptcy and the resultant increased likelihood of the sale of all or a fraction of its assets will place downward pressure on the value of similar assets, particularly when there are frictions in this secondary market.[3] Second, when a firm is in financial distress its demand for industry assets will likely diminish since it does not have, and can not easily raise, capital to purchase industry assets (Shleifer and Vishny (1992)). Since collateral plays an important role in raising debt financing, the reduction in collateral values associated with a firm's bankruptcy will increase the cost and reduce the availability of external debt finance. The collateral channel therefore implies that bankruptcies impose a negative externality on other industry participants through their impact on the value of collateral.

To analyze this collateral channel we focus on a single industry – airlines – and employ a unique identification strategy. This strategy involves utilizing information on collateral characteristics, collateral pricing, and the timing of airline bankruptcies in the following manner. Airlines in the U.S. issue tranches of secured debt to finance their operations. The debt is secured by a pool of aircraft serving as collateral. Using filing prospectuses, we identify the model type of all aircraft serving as collateral in each pool. For each tranche we obtain a time series of prices and obtain the

[2]In related literature, Chevalier and Scharfstein (1995, 1996) and Phillips (1995) examine a contagion effect from firms in financial distress to other industry participants through a product market pricing channel. They show that liquidity constrained firms – as proxied by those that undertook leveraged buyouts – tended to increase their product prices.

[3]See e.g. Pulvino (1998, 1999) for evidence on asset fire sales. Further support for fire sales is provided by Acharya et al. (2007) who show that recovery rates are lower when an industry is in distress.

dates and durations of all bankruptcy filings of airlines in the U.S. during the years 1994-2007.[4]

At heart, our identification strategy relies on analyzing the differential impact of an airline's bankruptcy on the price of tranches which are secured by aircraft of different model types. The collateral channel hypothesis predicts that tranches whose underlying collateral are of model types which have a large degree of overlap with the fleet of the bankrupt airline should exhibit larger price declines than tranches whose collateral has little overlap with the bankrupt airline's fleet. As explained above, an airline's bankruptcy and the increased likelihood of the sale of part or all of the airline's fleet will place downward pressure on the value of aircraft of the same model type. Furthermore, as in Shleifer and Vishny (1992), since demand for a given aircraft model type stems to a large extent from airlines who already operate that model type, an airline's financial distress and bankruptcy will reduce demand for the types of aircraft it operates in its fleet. For these two reasons – both increased supply of aircraft in the used market and reduced demand for certain aircraft – tranches secured by aircraft of model types exhibiting larger overlaps with the model types of the bankrupt airline's fleet should experience larger price declines.

By utilizing variation in the fleets of airlines going bankrupt and their degree of overlap with the type of aircraft serving as collateral for secured debt of other airlines, we can thus identify a collateral channel through which one firm's bankruptcy affects other firms in the same industry. Since we rely on the differential impact of bankruptcy on credit spreads of tranches secured by aircraft of different model types *within* an airline, this identification strategy alleviates concerns that the results are driven by an information channel effect in which bankruptcies convey negative information common to all firms in the industry. Moreover, we test our evidence for the collateral channel against alternative contagion-based explanations. For example, we show that are results are not driven by contagion through credit enhancers or through holders of tranche securities.

In the next section we describe in further detail the debt instruments used by airlines to issue secured debt and their development over time.

2. Airline Equipment Trust Certificates

ETCs and EETCs are aircraft asset-backed securities (ABS) that have been used since the early 1990s to finance the acquisitions of new aircraft.[5] Aircraft ABSs are subject to Section 1110

[4]We do not observe transaction prices of aircraft.

[5]Our discussion here draws heavily from Littlejohns and McGairl (1998), Morrell (2001), and Benmelech and Bergman (2008a) who provide an extensive description of the market for airline equipment trust certificates and its

protection which provided relief from the automatic stay of assets in bankruptcy to creditors holding a secured interest in aircraft, strengthening the creditor rights of the holders of these securities.

In a traditional ETC, a trustee issues equipment trust certificates to investors and uses the proceeds to buy the aircraft which is then leased to the airline. Lease payments are then used to pay principal and interest on the certificates. The collateral of ETCs typically included only one or two aircraft. For example, on August 24, 1990, American Airlines issued an Equipment Trust Certificate (1990 Equipment Trust Certificates, Series P) maturing on March 4, 2014. The certificates were issued to finance approximately 77% of the equipment cost of one Boeing 757-223 (serial number 24583) passenger aircraft, including engines (Rolls-Royce RB211-535E4B). The proceeds from the ETC issue were $35.5 million, with a serial interest rate of 10.36% and a credit rating of A (S&P) and A1 (Moody's).

Increasing issuance costs led to the development of Pass-Through certificates which pooled a number of ETCs into a single security which was then backed by a pool of aircraft rather than just one. While Pass-Through certificates increased diversification and reduced exposure to a single aircraft, the airline industry downturn in the early 1990s led to downgrades of many ETCs and PTCs to below investment grade and subsequently to a narrowed investor base.

During the mid 1990s ETCs and PTCs were further modified into EETCs – Enhanced Equipment Trust Certificates – which soon became the leading source of external finance of aircraft. EETC securitization have three main advantages compared to traditional ETCs and PTCs. First, EETCs have larger collateral pools with more than one aircraft type, making them more diversified. Second, EETCs typically have several tranches with different seniority. Third, a liquidity facility, provided by a third party such as Morgan Stanley Capital Services, ensures the continued payment of interest on the certificates for a predetermined period following a default, typically for a period of up to 18 months. EETC securitization therefore enhances the creditworthiness of traditional ETCs and PTCs by reducing the bankruptcy risk, tranching the cash flows, and providing temporary liquidity in the event of default.

Because of the varying loan-to-values, credit ratings, and yields associated with different tranches of EETCs, they are purchased by both investment grade and high yield institutional investors. These include insurance companies, pension funds, mutual funds, hedge funds and money managers. While the market for EETCs is not as liquid as that for corporate bonds, it is more liquid

historical evolution.

than the market for bank loans.[6]

Table 1 presents the characteristics and structures of three EETC issues in our sample. There are several tranches in each of the EETCs in Table 1. For each tranche we report the issue size (in $ million), yield, spreads (in basis points), final maturity date, Moody's and S&P tranche-specific credit rating, cumulative loan-to-value, and collateral description. For example, in the first EETC in the table (Fedex 1998-1), the most senior tranche (1-A) has a credit rating of Aa2/AAA, a cumulative loan-to-value ratio of 38.7%, and a credit spread of 125 basis points over the corresponding treasury. The least senior tranche in the Fedex 1998-1 issue (1-C) has a lower credit rating (Baa1/BBB+), a higher cumulative loan-to-value ratio (68.8%), and a credit spread of 155 basis points. All three tranches of Fedex 1998-1 are secured by the same pool of assets – 5 McDonnell Douglas MD-11F and 8 Airbus A300F4-605R.

3. Data and Summary Statistics

3.1. Sample Construction

We use SDC platinum to identify all secured tranches, Equipment Trust Certificates, Pass-Through Certificates, and Enhanced Equipment Trust Certificates issued by firms with four digit SIC codes 4512 (Scheduled Air Transportation), 4513 (Air Courier Services), and 4522 (Nonscheduled Air Transport) between January 1990 and December 2005. This results in 235 debt tranches issued in U.S. public markets. We collect data on tranche characteristics (i.e., issue size, seniority, final maturity, and whether the tranche is callable) from SDC platinum.

We supplement the SDC data with information collected from tranche filing prospectus obtained in EDGAR Plus (R) and Compact Disclosure. For each tranche, we obtain the serial number of all aircraft that were pledged as collateral from the filing prospectus. We are able to find full information about the aircraft collateral securing the issues for 198 public tranches. We match each aircraft serial number to the Ascend CASE airline database, which contains ownership information, operating information and information on aircraft characteristics for every commercial aircraft in the world.

We obtain tranche transactions data from the Fixed-Income Securities Database (FISD) compiled by Mergent, which is considered to be the most comprehensive source of bond prices.[7] The

[6] See Mann (2009).

[7] See Korteweg (2007) for a detailed description of the Mergent data.

National Association of Insurance Commissioners (NAIC) requires insurance companies to file all their trades in bonds with the NAIC. All transactions in our dataset, therefore, represent trades where at least one party was an insurance company.

Each observation of a transaction provides the flat price at which the transaction was made. We convert these prices into spreads by calculating the appropriate yield to maturity at the date of transaction, and then subtracting the yield of the duration matched Treasury.[8] For better comparability across tranches, we exclude from our sample tranches which were issued as floating rate debt.

We match each tranche transaction to the relevant airline's previous year's characteristics (i.e. size, market-to-book, profitability, and leverage) using Compustat data. Finally, we use Thomson's SDC Platinum Restructuring database to identify airlines that are in Chapter 7 or Chapter 11 bankruptcy procedures. Our final sample consists of 18,327 transactions in 127 individual tranches, representing 12 airlines during the period 1/1/1994 to 12/31/2007.

3.2. Tranche and Airline Characteristics

Panel A of Table 2 provides summary statistics for the 127 tranches in our sample. Summary statistics are calculated over the entire sample and are therefore weighted by the number of transaction observations per tranche. Throughout our analysis we use the tranche spread as our dependent variable. As Panel A shows, the mean tranche spread is 290.2 basis points and the standard deviation is 311 basis points. The mean tranche size in our sample is $274.4 million, with an average term-to-maturity of 16.9 years. There are at most 4 different layers of tranche seniority within an issue (where seniority=1 for most senior tranches and 4 for most junior). Further, as Panel A shows, 68% of the tranches in our sample are amortized, while 75% of the tranches in our sample have a liquidity facility – a feature common in Enhanced Equipment Trust Certificates. Finally, the average tranche loan-to-value ratio at time of issue is 0.54, ranging between 0.33 and 0.89.

Panel B of Table 2 provides summary statistics for the issuing airlines. The size of the average airline in our sample, measured as the book value of assets, is $14.2 billion. The average airline market to book ratio is 1.26, while their average profitability and leverage are 8.24% and 37%, respectively.[9]

[8] To calculate tranche yields, we distinguish between tranches that are amortized and those that have a balloon payment at maturity. This data is collected by reading the prospectuses of each issue.

[9] Appendix B provides description of construction and data sources for all variables used in the paper.

As in Benmelech and Bergman (2008 and 2009) and Gavazza (2008), we measure the redeployability of aircraft by exploiting aircraft model heterogeneity.[10] The redeployability measures are based on the fact that airlines tend to operate a limited number of aircraft models, implying that potential secondary market buyers of any given type of aircraft are likely to be airlines already operating the same type of aircraft. Redeployability is, therefore, proxied by the number of potential buyers and the 'popularity' of an aircraft model type.

Using the Ascend CASE database, we construct two redeployability measures in the following manner. For every aircraft type and sample-year we compute 1) the number of non-bankrupt operators flying that aircraft model type; and 2) the number of aircraft of that type used by non-bankrupt operators. This process yields two redeployability measures for each aircraft-type and each sample-year. To construct the redeployability measures for a portfolio of aircraft serving as collateral for a particular tranche, we calculate the weighted average of each redeployability measure across all aircraft in the collateral portfolio. For weights in this calculation, we use the number of seats in an aircraft model type – a common proxy for aircraft size (and value). Panel C of Table 2 provides descriptive statistics for our two redeployability measures. As can be seen, the redeployability measure based on number of aircraft has an average value of 1,392.9 aircraft. Furthermore, on average, there are 135.9 potential buyers for aircraft serving as collateral for secured tranche issue.

Finally, we add additional variables that capture the health of the airline industry. These variables are jet fuel price, number of bankrupt airlines, number of non-bankrupt or healthy airlines, The book value of bankrupt airlines divided by the book value of all airlines, as well as the book value of non-bankrupt airlines divided by the book value of all airlines. Panel D report summary statistics for each of these variables.

3.3. Identifying Bankruptcy Shocks

We construct two measures of shocks to collateral driven by airlines entering bankruptcy. For each aircraft type and calendar day in our sample we calculate (1) the number of airlines operating that particular model type which are in bankruptcy, $Bankrupt\ Buyers$; and (2) the number of aircraft of that particular type which are operated by airlines in bankruptcy, $Bankrupt\ Aircraft$.[11] Increases

[10] Appendix A provides a detailed description of the construction of this redeployability measure.

[11] We calculate these measures using beginning and end dates of airline bankruptcies in the U.S. from SDC Platinum.

in the first measure capture reductions in demand for a given model type, as airlines tend to purchase aircraft of model types that they already operate. Increases in the second measure are associated with an increase in the supply of a given aircraft model type likely to be sold in the market as bankrupt airlines liquidate part or all of their fleets. Since changes in aircraft ownership are relatively infrequent, ownership information of aircraft is updated at a yearly rather than daily frequency. However, the two measures may change at a daily frequency due to airlines entering or exiting bankruptcy. In Appendix A, figures A1 and A2 provide a timeline of airline bankruptcies in the United States and the total number of aircraft operated by bankrupt US airlines over the sample period.

Figures 1 and 2 provide a graphic illustration of the two measures for the Boeing 737 and Boeing 747 model types. For each model type, the figures thus show the evolution over time of the number of operators in bankruptcy operating each of these models, as well as the number of aircraft operated by bankrupt airlines. The figures clearly show the deterioration of industry conditions in the latter part of the sample period. Further, while there are some commonalities in the trends between the model types, there are also large differences between model types in both measures. Thus, for example, while the number of bankrupt B747 aircraft increased during the first part of 2004, the number of bankrupt B737 aircraft decreased during this period. This variation between model types stems from bankruptcies of airlines operating different fleets composed of different model types. As discussed in section 1, it is this variation, and the differences in the types of aircraft used as collateral, which enables identification of the collateral channel.

To construct the two bankruptcy measures for a portfolio of aircraft serving as collateral for a particular tranche, we calculate the weighted average of the aircraft type measures across all aircraft in the portfolio, using the number of seats in each aircraft as weights.

Panel A of Table 3 provides summary statistics for the two measures, Panels B and C display the evolution of the bankrupt buyers and bankrupt aircraft measures over time. As can be seen, over the entire sample period, the average value of $Bankrupt\,Buyers$ was 0.809 indicating that the average aircraft in a tranche had 0.809 potential buyers that were in bankruptcy. Similarly, the average value of $Bankrupt\,Aircraft$ was 43.86 aircraft indicating that their were 43.86 aircraft operated by bankrupt airlines of the same model type as the average aircraft serving as collateral in a debt tranche.

4. Empirical Analysis

4.1. Univariate Analysis

As an initial step, it is instructive to conduct the analysis using simple comparison-of-means tests. Panel A of Table 4 displays average tranche credit spreads of both bankrupt and non-bankrupt airlines. There are 1,011 transactions in 43 tranches of four bankrupt airlines. As would be expected, credit spreads of tranches issued by airlines that are currently in bankruptcy are higher than spreads of solvent airlines. The mean credit spread of a bankrupt airline is 531.7 basis points compared to a mean tranche spread of 276.1 basis points for non-bankrupt airlines (t-statistic for an equal means test=2.81).

As a first, simple test of the credit chanel, we focus only on airlines that are *not* in bankruptcy, and split this sub-sample between airlines with fleets that do not have any bankrupt potential buyer, and airlines with at least one bankrupt potential buyer for their fleet. As described in the previous section, an airline is considered to be a potential buyer of a particular aircraft if in its fleet it operates aircraft of the same model type. Focusing only on non-bankrupt firms ensures that credit spreads are not contaminated by the direct association of bankruptcy and credit spreads.

Out of the 17,316 transactions in non-bankrupt airlines tranches there are 8,324 transactions with no bankrupt potential collateral buyers, and 8,992 transactions with at least one bankrupt potential collateral buyers. Panel B of Table 4 compares credit spreads of tranches that do not have any bankrupt potential buyers, and tranches with at least some bankrupt potential buyers for their pledged collateral. As can be seen in the table, the mean tranche credit spreads of a non-bankrupt airline that has no bankrupt buyers is 208.0 basis points compared to a mean tranche spread of 339.0 basis points for non-bankrupt airlines with some bankrupt potential buyers (t-statistic for an equal means test=7.48). Thus, consistent with a collateral channel, tranches of airlines secured by collateral with potential buyers that are in bankruptcy have a lower value than tranches where all potential buyers are not in bankruptcy.

While still focusing only on non-bankrupt airlines, Panel C of Table 4 refines the analysis in Panel B by conditioning the credit spread differential on tranche seniority levels. We conjecture that the collateral effect will be larger in more junior tranches due to their higher sensitivity to the value of the underlying collateral. Panel C splits the sample to four levels of seniority (1=most senior 4=most junior), and compares the mean credit spread between tranches with no bankrupt potential buyers and tranches with some bankrupt potential buyers for each of the seniority levels. The first four columns of the panel report credit spreads and number of observations in each category (in parentheses), as well as t-tests for an equal means test across and within seniority levels.

As Panel C of Table 4 demonstrates, the difference between credit spreads of tranches with and without bankrupt potential buyers is the highest among the most junior tranches, and monotonically decreases with tranche seniority. For the most senior tranches the spread difference is 95.0 basis points, while the differences for seniority levels 2 and 3 (i.e mezzanine seniority) are 195.5 basis points and 297.4 basis points, respectively. Finally, among the most junior tranches the spread differential is much higher and equals 1112.9 basis points. All differences are statistically significant at the one percent level.

In the last three columns of Panel C of Table 4 we use a differences-in-differences approach. In each of these columns we report the difference between the means of credit spreads of tranches with different seniority (1 vs. 2, 1 vs. 3, and 1 vs. 4) and the corresponding t-values for equal means test. These differences in seniority-based credit spreads are reported separately for tranches with bankrupt potential buyers for their underlying collateral and for tranches without bankrupt potential buyers. As can be seen in the table, we find that the seniority-differential in spreads is much higher for tranches with some bankrupt potential buyers. As the last column of Panel C demonstrates, among tranches with no bankrupt potential buyer, the spread differential between most and least senior tranches is a statistically significant 124.5 basis points. In contrast, moving from most senior to most junior tranches with some bankrupt potential buyers is associated with a spread increase of a statistically significant 1142.5 basis points.

4.2. Regression Analysis

We begin with a simple test of the collateral channel hypothesis by estimating different variants of the following baseline specification:

$$
\begin{aligned}
Spread_{i,a,t} \;&=\; \beta_1 \times log(1 + Bankrupt\,Buyers)_{i,a,t} + \beta_2 \times Bankruptcy_{i,a,t} \\
&+\; \beta_3 \times log(1 + Redeployability)_{i,a,t} + \mathbf{X}_{i,a,t}\boldsymbol{\gamma} + \mathbf{b}_i\boldsymbol{\delta} + \mathbf{c}_a\boldsymbol{\eta} + \mathbf{d}_y\boldsymbol{\theta} \\
&+\; (Bankruptcy_{i,a,t} \times \mathbf{b}_i)\boldsymbol{\kappa} + (Bankruptcy_{i,a,t} \times \mathbf{c}_a)\boldsymbol{\psi} + \epsilon_{i,a,t},
\end{aligned} \tag{1}
$$

where *Spread* is the tranche credit spread, subscripts indicate tranche (i), airline (a), and transaction date (t); *Bankrupt Buyers* is the weighted average of the number of bankrupt operators currently using the collateral pool; *Bankruptcy* is a dummy variable that equals one if the issuer of the tranche is bankrupt on the date of the transaction; *Redeployability* is one of our two measures of the redeployability of the collateral pool; $\mathbf{X}_{i,a,t}$ is a vector of tranche characteristics that includes an amortization dummy, a dummy for tranches with liquidity facility, ranking of the tranche seniority, tranche issue size, a dummy for tranches with a call provision, and the tranche term-to-maturity; $\mathbf{b}_i$ is a vector of tranche fixed-effects; $\mathbf{c}_a$ is a vector of airline fixed-effects; $\mathbf{d}_y$ is a vector of year fixed-effects; $Bankruptcy_{i,a,t} \times \mathbf{b}_i$ is a vector of interaction terms between tranche fixed-effects and the Bankruptcy dummy; $Bankruptcy_{i,a,t} \times \mathbf{c}_a$ is a vector of interaction terms between airline fixed-effects and the Bankruptcy dummy; and $\epsilon_{i,a,t}$ is the regression residual. We report the results from estimating different variants of regression 1 in Panel A of Table 5.[12] Tables throughout the paper report standard errors that are clustered at the tranche level (in parentheses).

The first column in Panel A Table 5 reports the coefficients from estimating a simple version of regression 1, without any of the fixed-effects or the interaction terms. As would be expected, tranche spreads of airlines in bankruptcy are higher than those out of bankruptcy – the coefficient on the Bankruptcy dummy, β_2, equals 126.6 and is statistically significant. Further, consistent with Benmelech and Bergman (2009), we find that more redeployable collateral, proxied by the number of world-wide operators using the collateral pool, is associated with lower spreads. Finally, after controlling for bankruptcy and redeployability, and consistent with a collateral channel, β_1 is positive and significant at the one percent level. Increases in the number of bankrupt potential buyers for a given collateral pool – and hence commensurate reductions in demand for the assets in that pool – are associated with larger tranche credit spreads. The economic effect of the collateral channel is sizeable – as Panel C shows moving from the 25th percentile to the 75th percentile of the number of bankrupt buyers results in a credit spread that is higher by 387.2 basis points.

In the rest of the specifications reported in Panel A we add year and either tranche or airline fixed-effects, and in some specifications include interactions between tranche or airline fixed-effects and the bankruptcy dummy to soak up any direct effect of bankruptcy on tranche spreads. As can be seen, the coefficient on the number of bankrupt buyers, β_1, is consistently positive and statistically significant at the one percent level. While the estimate of β_1 is lower in these specifications, it

[12]For brevity, we do not report the coefficients of the tranche characteristics in this table. We investigate their effects in the next tables.

is still economically significant: as Panel C shows, moving from the 25th percentile to the 75th percentile of the number of bankrupt buyers in these specifications results in a credit spread that is higher by between 147.1 and 238.2 basis points.

Panel B of Table 5 repeats the analysis in Panel A using our second measure of shocks to collateral values, *Bankrupt Aircraft*, that is based on the number of aircraft operated by bankrupt airlines that overlap with the collateral channel. As can be seen, an increase in the number of aircraft operated by bankrupt airlines is associated with higher credit spreads of tranches employing similar aircraft model types as collateral. Although the magnitudes of the coefficients are smaller than those using the *Bankrupt Buyers* measure (see Panel C), the results are still statistically and economically significant.

4.3. The Collateral Channel: Evidence from Prices of Non-Bankrupt Airlines Tranches

The analysis presented in Table 5 shows that bankrupt potential buyers of collateral lead to higher credit spreads, controlling for bankruptcy status and for interaction terms between being in bankruptcy, and airline, and tranche fixed-effects. While these specifications are likely to soak up non time-varying effects related to the bankruptcy status of a tranche, we now move to focusing only on non-bankrupt airlines. Thus, we refine our analysis by focusing on tranches of non-bankrupt airlines and examine how, while solvent, their credit spreads respond to the bankruptcy of airlines operating fleets comprised of model types that overlap with the tranche collateral pool. We estimate different variants of the following specification:

$$\begin{aligned} Spread_{i,a,t} \quad &= \quad \beta_1 \times log(1 + Bankrupt\,Buyers)_{i,a,t} + \beta_2 \times log(1 + Redeployability)_{i,a,t} \\ &+ \quad \mathbf{I}_t\boldsymbol{\tau} + \mathbf{X}_{i,a,t}\boldsymbol{\gamma} + \mathbf{Z}_{a,y-1}\boldsymbol{\xi} + \mathbf{R}_t\boldsymbol{\pi} + \mathbf{b}_i\boldsymbol{\delta} + \mathbf{c}_a\boldsymbol{\eta} + \mathbf{d}_y\boldsymbol{\theta} + \epsilon_{i,a,t} \\ for\,all \quad & Bankruptcy_{i,a,t} = 0, \end{aligned} \tag{2}$$

where *Spread* is the tranche credit spread; subscripts indicate tranche (i), airline (a), and transaction date (t); *Bankrupt Buyers* is a weighted average of the number of bankrupt operators currently using the collateral pool; *Bankruptcy* is a dummy variable that equals to one if the issuer of the tranche is bankrupt on the date of the transaction; and *Redeployability* is one of our two measures of the redeployability of the collateral pool. $\mathbf{I}_t$ is a vector which includes two time-varying variables that capture the health of the airline industry – the price of jet fuel and the number of

U.S. bankrupt airlines; $\mathbf{X}_{i,a,t}$ is a vector of tranche characteristics that includes an amortization dummy, a dummy for tranches with a liquidity facility, the ranking of tranche seniority, tranche issue size, a dummy for tranches with a call provision, and the tranche term-to-maturity; $\mathbf{Z}_{a,y-1}$ is a vector of beginning-of-year airline characteristics that includes the airline size, market-to-book ratio, profitability, and leverage; $\mathbf{R}_t$ is a vector of interest rate controls that includes the 1-year yield on U.S. Treasury, the term spread between the 7-year and 1-year Treasury, and the default spread between Baa and Aaa rated bonds.[13] $\mathbf{b}_i$ is a vector of tranche fixed-effects, $\mathbf{c}_a$ is a vector of airline fixed-effects, $\mathbf{d}_y$ is a vector of year fixed-effects, and $\epsilon_{i,a,t}$ is the regression residual. We report the results from estimating different variants of regression 2 in Table 6. As before, we cluster standard errors (reported in parentheses) at the tranche level.

Column 1 of Table 6 presents the results of regression 2 using only year fixed effects. As can be seen, the positive relation between the number of bankrupt operators and credit spreads continues to be statistically significant even after controlling for a host of tranche and firm level control variables. Thus, consistent with the collateral channel, increases in the number of potential buyers of collateral who are in bankruptcy are associated with increases in the spread of tranches backed by this collateral.

Turning to the control variables, we find that as in Benmelech and Bergman (2009), the negative effect of redeployability is still significant once tranche and airline level controls are added to the regressions. While the coefficient on fuel price is positive, it is not statistically significant. However, we find statistically significant evidence that when more airlines are in bankruptcy, tranche spreads tend to be higher.

Examining the tranche level control variables, we find that amortized tranches have lower spreads, which is to be expected as their repayment schedule is more front loaded and hence their credit risk is lower. Likewise, tranches that are enhanced by a liquidity facility have lower spreads, and more senior tranches command lower spreads as well.[14] We also find that larger tranches are associated with lower spreads, consistent with larger tranches being more liquid (see e.g. Bao, Pan, and Wang (2008)). We do not find a statistically significant relation between spreads and having a call provision. Finally, tranches with longer term-to-maturity have higher credit spreads.

[13] All yield data is taken from the Economic Research Federal Reserve Bank of St. Louis website at http://research.stlouisfed.org/fred2/. For brevity, we do not report the coefficients of the interest rates variables.

[14] Recall that seniority variable is coded as a discrete variable between 1 and 4 with 1 being the most senior tranche, explaining the negative coefficient on the variable in the table.

The airline level control variables in Column 1 show that, as would be expected, airlines that are more profitable or less leveraged have lower credit spreads. This effect is economically significant, with a one standard deviation increase in profitability reducing the tranche credit spread by 67.74 basis points, and a one standard deviation increase in leverage increasing the spread by 68.13 basis points.[15] Finally, we find that airlines with high market to book ratios have lower higher credit spreads.

Column 2 of Table 6 repeats the analysis in Column 1 while adding airline fixed effects to the specification. As can be seen, the results remain qualitatively and quantitatively unchanged: increases in the number of potential buyers that are in bankruptcy leads to an increase in the tranche credit spread. Column 3 repeats the analysis but adds tranche level fixed effects to the specification and hence control for unobserved heterogeneity amongst tranches. Naturally, in the tranche fixed effects specification the tranche level controls are dropped as they do not vary over time and hence are fully absorbed by the fixed effects. As can be seen in the table, we continue to find a positive relation between the number of buyers in bankruptcy and credit spreads.

We also note that the coefficients on the redeployability measures are still negative as in Benmelech and Bergman (2009), but no longer statistically significant once we include tranche fixed effects – a result recurrent throughout the analysis. To understand this note that, in the time series, variation in redeployability and the bankruptcy measures is driven by airlines entering or exiting bankruptcy; when a potential buyer airline enters bankruptcy, the number of bankrupt buyers increases by one, while the redeployability measure decreases by one. However, the redeployability measure also varies in the time series due to new airlines starting up and increasing the number of potential buyers. The fact that with tranche fixed effects the number of bankrupt buyers variable is significant while the redeployability measure is not, suggests that in the time series, the important variation that drives changes in spreads is not the addition of new airlines but rather airlines entering or exiting bankruptcy.

In columns 4 through 6 we repeat our analysis using our second measure of shocks to collateral values, *Bankrupt Aircraft*, that is based on the number of aircraft that overlap with the tranche collateral pool that are operated by bankrupt airlines. While our results are statistically weaker

[15] Also, to the extent that there is some slack in the pricing of the debt – i.e. that the market for airline tranches is not perfecetly competitive, but rather results in part from a negotiation between the airline and buyers of it debt capital – this results is also consistent with lower bargaining power of the 'weak' issuing airlines who are willing to place the debt at lower prices.

using this measure, they are consistent with the previous estimates when we control for airline or tranche (in addition to year) fixed effects – the *Bankrupt Aircraft* measure is significantly related to higher tranche credit spreads. Consistent with the collateral channel, increases in the number of aircraft operated by bankrupt airlines are associated with higher credit spreads of tranches employing similar aircraft model types as collateral.

4.4. Robustness: Controlling for Industry Conditions

One concern with our analysis is that we are capturing an adverse industry shock affecting all airlines in the industry. First, it should be noted that our identification strategy relies on the differential impact of an airline's bankruptcy on the credit spreads of tranches which are secured by different aircraft model types, and as such an industry shock is unlikely to drive our findings. Second, our results in Table 6 are robust to the inclusion of industry control variables such as fuel price and the number of bankrupt airlines. Nevertheless, in order to further alleviate this concern we use a battery of industry controls that include, in addition to jet fuel price and number of bankrupt airlines, also the asset share of bankrupt airlines (defined as the book value of the assets of bankrupt airlines divided by the total book value of airlines in the U.S), and the relative number of bankrupt airlines (number of bankrupt airlines divided by the total number of airlines). Likewise, in different specifications we also control for the complements of these variables: the number of healthy airlines, as well as the asset share and the relative number of healthy airlines.

Table 7 reports the results from estimating regression 2 with tranche fixed-effects and an augmented vector of time-varying industry controls. For brevity, we report results with the bankrupt-based industry variables using the number of bankrupt buyers, and the healthy-based industry variables using the number of bankrupt aircraft.[16] As can be seen, the number of bankrupt airlines as well as the relative number of bankrupt airlines have the predicted positive sign and are statistically significant, while the asset share of bankrupt airlines is not significant.[17] Importantly, as Table 7 demonstrates, our results are robust to the inclusion of all of the industry controls. In fact the coefficient β_1 becomes even stronger when we add additional industry controls that potentially soak up more of the time-series variation in tranche credit spreads.

[16] Clearly, controlling for the asset share and relative number of healthy airlines is equivalent to using the complement variables of the asset share and relative number of *bankrupt* airlines.

[17] We add these controls one at a time as they are all highly collinear. In unreported results we include all industry controls together and our results hold for both measures of the collateral channel. Since the industry controls are highly collinear, their significance disappears when they are added together due to multicollinearity.

Another concern is that while we control for a battery of industry controls, it is still possible that the negative information provided by the bankruptcy of an airline with a given fleet is of greater relevance for particular airlines. According to this view, the information channel may still be operative since some airlines may have different sensitivities to industry conditions than others. We address this concern in Table 8. We add to the analysis in Table 6 a dummy variable for the post 9/11/2001 period, in which average American airline profitability fell drastically.[18] We use the post-9/11 dummy as an additional industry control and indeed find that credit spreads are much higher in the period following the 9/11 attacks.

Moreover, we interact airline fixed-effects with the 9/11 dummy to control for airline heterogeneity in their response to this severe industry shock. As Table 8 shows, the coefficient of β_1 is still statistically significant and is again stronger than in our baseline regressions in Table 6.[19] To summarize, our analysis is robust to various industry controls even when we allow airlines to have heterogenous response to industry conditions.

4.5. Robustness: Reverse Causality

A more subtle concern is about the direction of causality. We argue that bankruptcies of potential buyers lead to declines in asset values, increasing the cost of debt financing of non-bankrupt airlines. However, an alternative explanation is that an adverse shock to the productivity of some aircraft results in the bankruptcy of airlines using them, as well as a decline in value and increased cost of capital for other users of these aircraft.

The reverse causality explanation is best exemplified with the case of the Arospatiale-BAC Concorde – the famous supersonic passenger airliner. While the Concorde was designed for supersonic long-haul trips, such as between London and New York, it was used in the late 1970s by Braniff International Airways on shorter range subsonic flights within the United States. The flights were usually less than 50% booked, leading Braniff to terminate Concorde operations in May 1980. Braniff filed for bankruptcy in May 1982. To the extent that Braniff's bankruptcy reflected a failed strategy associated with operating the Concorde, the reverse causality argument would suggest that market priors about the viability of the Concorde aircraft would be updated, resulting ultimately in higher costs of capital for other users of this aircraft.

[18] Benmelech and Bergman (2008) report that the average profitability of airlines in their sample was 13.31% in the period 1994-2000, and only 4.77% in the period 2001-2005.

[19] We obtain similar results using all other industry controls which we do not report for brevity.

We deal with the reverse causality argument suggested by the Braniff case empirically in Table 9. It is important to note, however, that while the Concorde is a specialized aircraft with limited efficient uses outside supersonic long-haul travel, all the aircraft used as collateral in our sample are commonly used general-purpose aircraft. Our sample includes the most popular models of Airbus (A300, A310, A319, A320, A321, A330), Boeing (B737, B747, B757, B767, and B777) and MacDonald Douglas (MD11, MD80), as well as regional aircraft made by BAE and Embraer. None of these models is specialized or esoteric, and none of the models experienced an idiosyncratic shock during this time-period making it less desirable. Nevertheless, we address the reverse causality concern empirically.

We construct dummy variables for each of the different aircraft models that take the value of one if there is at least one aircraft of that model in the tranche collateral pool. We then rerun our regressions with tranche fixed-effects as well as year×model fixed-effects, allowing different aircraft models to have a time-varying effect on credit spreads. As the first two columns of Table 9 show, our results are even stronger using both the bankrupt buyers and bankrupt aircraft measures. We also run the regression for tranches that employ only Airbus and Boeing aircraft as collateral (column 3) or even only Boeing aircraft (column 4) – Airbus and Boeing are the leading aircraft manufacturers in the world and their aircraft are both general-purpose and highly reliable. In our sample, there are 105 tranches that use only Airbus and Boeing, and 69 tranches using only Boeing. In focusing on these subsamples, we are identifying off of variation in the number of potential buyers of Airbus and Boeing aircraft that are in bankruptcy. As Table 9 demonstrates, our results hold both for Airbus and Boeing, as well as only for Boeing. Our results therefore hold also for general purpose, popular aircraft for which it is unlikely that new information about productivity is being revealed.

For additional robustness, we further control for the aircrafts' main usage in our analysis. The main difference between aircraft in our collateral pool is whether they are short-haul narrow-bodied (e.g. A319, A320, A321, B737, B757, etc.) or long-haul wide-bodied (A300, A310, A330, B747. B767, B777).[20] We construct a dummy variable that equals one for wide-bodied aircraft and interact it with month-year fixed-effects (i.e. every month-year combination in our data corresponds to a particular dummy variable). As the last two columns of Table 9 show, our results still hold. Again, it is therefore unlikely that our results are driven by new information about the productivity associated with the main usage of the aircraft models used as collateral.

[20] A narrow-body aircraft is one with a single passenger aisle, while a wide-body aircraft has two such aisles.

4.6. Robustness: Liquidity Facility and Credit Enhancement

As described in Section 2, 75% of the tranches in our sample are Enhanced Equipment Trust Certificates (EETCs) which include a liquidity facility that enhances their credit worthiness. The credit enhancer, which is typically a financial institution, commits to pay interest payments in case of default for a prespecified amount of time, usually 18 months. The standard reason given for such an enhancement is to enable a more orderly sale of aircraft, providing 'breathing room' to prevent fire sales. For example, in an EETC issued by Continental Airlines in 2002 (2002-1) the primary liquidity facility is provided by Landesbank Hessen-Thüringen Girozentrale, supplemented by a liquidity facility from Merrill Lynch Capital Services Inc. Likewise, in EETC Series 2000-3 issued by U.S Airways in 2000, the liquidity facility was provided by Morgan Stanley Capital Services, while the 1998-1 Series EETC issued by U.S. Airways had its liquidity facility provided by the Chicago Branch of ABN ARMO Bank N.V.

Since the liquidity facility credit enhancements are provided by third parties and not the airline itself, they do not expose the tranche to further airline liquidity risk. Still, our results could be explained by a contagion effect through the quality of credit enhancers if, for some reason, tranches backed by aircraft of similar type were enhanced by the same institutions or by institutions with stronger links.[21] We control for the provision of a liquidity facility in our analysis above and our results are always robust. Nevertheless, to deal with the concern of contagion through liquidity enhancers, we rerun our regressions separately for tranches without a liquidity facility.

As Table 10 demonstrates, our results continue to hold for both measures of redeployability, even amongst those tranches with no liquidity enhancement, and hence without the possibility of contagion through credit enhancers. The results hold when we include airline or tranche fixed-effects, in addition to year fixed-effects. Indeed, we find that β_1, the coefficient on our *Bankrupt Buyers* and *Bankrupt Aircraft* measures, is larger for tranches without liquidity enhancements. Put differently, spreads of tranches without a liquidity enhancement are more sensitive to bankruptcy shocks. This is to be expected: since in default there is no liquidity enhancement, fire sales are more likely, and hence having more potential buyers in financial distress (i.e. *Bankrupt Buyers* is high) is more costly. Similarly, attempting to sell collateral when similar assets are already flooding the market (i.e. *Bankrupt Aircraft* is high) is costly as well.

[21] As a related example, during the peak of the financial crisis in 2008, concerns about Ambac and MBIA led to downgrades of CDO tranches insured by these companies.

Additionally, we find that credit spreads of tranches without a liquidity facility are more sensitive to airline profitability and leverage as compared to tranches with such a liquidity facility. Again, this is to be expected, since the higher probability of fire sales in default associated with the lack of a liquidity facility implies that airline financial condition becomes more important in determining spreads.

4.7. Robustness: Accounting for Contagion through Security Holders

Another potential contagion effect arises through holders of ETC and EETC securities. Since the Mergent Fixed-Income Securities Database (FISD) used in our analysis contains transactions undertaken by insurance companies, it is possible that when airlines enter financial distress, insurance companies operating subject to prudent investment regulations or guidelines sell their holdings of tranches issued by the distressed airlines. In this case, the contagion operates through fire-sales of risky-airline securities and not necessarily though an underlying collateral channel.

We address the concern of contagion through holders of securities in a number of ways. First, for each observation in our dataset we have information on whether the reported transaction was a purchase or a sale by the reporting insurance company. We conjecture that contagion through holders of securities should be reflected mainly in sell-side transactions in which a binding balance sheet or investment policy constraint triggered by equity losses forces an insurance company to rebalance its portfolio by selling part of its holdings of corporate debt. We therefore subdivide our sample based on whether a transaction represents a sale or a purchase of a tranche by an insurance company and rerun our regressions in each subsample separately. As Table 11 shows, we find that both of our measures, *Bankrupt Buyer* (columns 1-4) and *Bankrupt Aircraft* (columns 5-8), are statistically significant and positively related to credit spreads in both subsamples. Indeed, we find that the coefficient on the bankruptcy measures are twice as large in the 'buy' sample as compared to the 'sell' sample, in contrast to the contagion by holders of securities hypothesis.

As an additional method of dealing with the alternative hypothesis of contagion through security holders, we employ data on tranche credit rating at the time of the transaction. We conjecture that contagion due to regulation or investment policy constraints should be concentrated in downgrades of corporate bonds from investment to non-investment grade. We therefore match each tranche transaction to its Moody's credit rating at the time of transaction using Moody's Default Risk Service (DRS) Database. We then subdivide our sample based on the rating of the tranche at the time of the transaction, running our regressions on the subsample of transactions of investment grade tranches (i.e. the top 10 credit rating notches: Aaa through Baa3), the subsample of transactions of tranches rated Aaa-Aa3 (the top 4 notches), and the subsample of transactions of tranches rated Aaa (the top notch). Although examining subsamples separately naturally reduces the sample size in each individual regression, and considerably so for the third subsample in which we only examine Aaa tranches, as Table 12 shows, we find that our results continue to hold for both Buy and Sell transactions in all three subsamples: investment grade (columns 1-2); Aaa-Aa3 (columns 3-4), and Aaa (columns 5-6). Thus, our results hold for both purchases and sales of tranches that are very highly rated, alleviating concerns about contagion through rating-based regulation fire-sales.[22]

As an additional robustness check, we have also excluded the last two years of our sample from our regressions to ensure that any unusual circumstances related to forced sales during the current financial crisis are not driving our results. Our results (columns 7-8 of Table 12) continue to hold using this slice as well.[23] Hence, our results are not driven by the sell-off of asset-backed securities of 2007-2008.

Moreover, in an attempt to control for the identities of the insurance companies transacting in tranches, we split the sample into transactions made by Life Insurance firms and those made by Property & Casualty firms.[24] There are 4,780 transactions made by Property & Casualty firms and 11,297 transactions by Life Insurance firms. As Table C1 in Appendix C demonstrates, our results are almost identical across insurance companies types. Using both measures of redeployability, we obtain very similar statistically significant relations between either the number of bankrupt buyers or the number of bankrupt aircraft and tranche credit spreads. Our results, therefore, do not appear to be driven by institutional details specific to a particular type of insurance company.

Finally, in 3,205 transactions in our data we were able to identify the vendor (broker or dealer) selling or buying the security from the insurance company. There are 45 individual vendors (typically, investment banks, commercial banks, or brokers) in this subsample. Using this subsample, the last four columns of Table 6 report regression results from estimating the effect of both *Bankrupt Buyers* (columns 5-6) and *Bankrupt Aircraft* (columns 7-8) on credit spreads, controlling for either airline+year or tranche+year fixed effects as well as vendor fixed effects. As Table C1 shows,

[22] While our results hold using both measures of redeployability, for brevity we only report results using the *Bankrupt Buyers* measure.

[23] Our results hold whether we use the 1994-2005 or the 1994-2006 periods. While the year 2007 arguably marks the beginning of the crisis, we exclude trades during the year 2006 as well out of an abundance of caution.

[24] The FISD data does not provide us the identity of the insurance companies – only their type.

our results hold in this cut of the data as well. Consistent with the collateral channel, both the *Bankrupt Buyers* and *Bankrupt Aircraft* are both positively related to tranche credit spreads, even when controlling for vendor fixed effects.

In summary, our results are not likely to be driven by fire-sales, rating-based investment rules and regulations, insurance company type or the identity of the vendor. We conclude that contagion through investors does not seem to explain the strong relation between bankruptcy shocks and credit spreads.

4.8. The Collateral Channel, Tranche Seniority and LTV

We continue our analysis in Table 13 by examining the effects of tranche seniority and Loan-to-Value (LTV) ratios in the collateral channel. We hypothesize that the negative relation between the measure of the number of bankrupt buyers or number of bankrupt aircraft and credit spreads should be concentrated in more junior tranches, or equivalently in tranches with high LTV, since these are the ones which, upon default, would be more exposed to drops in the value of the underlying collateralized assets. As a first test of this hypothesis, Column 1 of Table 13 presents the results of regression 2 while adding an interaction variable between the measure of the number of bankrupt buyers, *Bankrupt Buyers*, and the seniority of each tranche.[25] The regression includes either airline- or tranche- (as well as year-) fixed-effects and standard errors are clustered at the tranche level.

As can be seen in column 1 of Table 13, we find that the coefficient on the interaction term between *Bankrupt Buyers* and tranche seniority is positive and statistically significant. As hypothesized, we thus find that increases in the number of bankrupt potential buyers increases the spread of junior tranches more than that of senior tranches. The differential effect of moving from zero to one bankrupt buyer in most senior as compared to most junior tranches is 106.01 basis points.[26] We repeat the analysis in column 2 controlling for tranche fixed effects and obtain similar results.[27] Furthermore, we stratify the data between senior tranches (seniority levels 1 and 2) and junior tranches (seniority levels 3 and 4) and estimate regression 2 separately for senior and junior tranches. As the coefficients on the *Bankrupt Buyers* measure in columns 3 and 4 indicate, junior tranches are much more sensitive to the number of bankrupt buyers, consistent with the interaction

[25] We obtain similar results using *Bankrupt Aircraft* which we do not report fro brevity.

[26] To see this, we calculate the joint effect of seniority and number of bankrupt buyers on credit spreads using the total differential of both the level of *Bankrupt Buyers* as well as the interaction with seniority. Thus, this differential is $-163.798 \times 0.301 + (171.992 \times 0.301 \times 4) - (171.992 \times 0.301 \times 1) = 106.01$

[27] Clearly, the variable seniority is being absorbed by the tranche fixed-effects in this specification.

results.

In the last four columns of Table 13 we repeat the analysis but categorize tranches based on loan-to-value ratios (LTVs) rather than seniority. LTVs are obtained from the tranche filing prospectus, and reflect cumulative loan-to-value ratios as of the time of issue.[28] Specifically, these are defined as the ratio between the sum of the principal amount of that tranche and all tranches senior to it, divided by an appraisal of the value of the assets serving as collateral.

We begin with specifications in which LTV is interacted with *Bankrupt Buyers* (columns 5 and 6) and find results that are consistent with the seniority interactions – credit spreads are more sensitive to the *Bankrupt Buyer* measure amongst tranches with high LTVs. Increasing the *Bankrupt Buyer* measure from zero to one for tranches at the 25th percentile of LTV (0.41) reduces tranche credit spreads by 10.7 basis points. In contrast, the same increase for tranches at the 75th percentile of LTV (0.66) causes tranche spreads to decrease by 44.15 basis points. In the last two columns of Table 13 we stratify the sample into tranches with LTVs below 0.5 (column 7) and those with LTVs at or above 0.5 (column 8).[29] As columns 7 and 8 demonstrate, credit spreads of tranches with LTVs higher than 0.5 are more sensitive to the number of bankrupt buyers than those with LTV lower than 0.5. Indeed, the coefficient on *Bankrupt Buyers* more than doubles in high as compared to low LTV subsamples.

We investigate the transmission of the collateral channel further in Table 14 by studying the joint impact of airline financial health and the number of bankrupt buyers on tranche spreads. We hypothesize that the positive relation between the number of potential buyers in bankruptcy and tranche credit spreads should be larger for airlines with low profitability. Less profitable airlines are more likely to be in financial distress, making the value of their tranches more sensitive to the liquidation value of their collateral. Further, as in the previous section, we expect that the effect should be more pronounced amongst more junior, high LTV tranches. We therefore introduce an interaction variable between profitability and *Bankrupt Buyers* into the specification of regression 2. Similar to the analysis in Table 13, we run the analysis separately for senior and junior tranches (columns 1 and 2) as well as for tranches with LTVs below and above 0.5 (columns 3 and 4).[30] Each

[28] We are unable to obtain dynamic LTVs along the economic life of the tranche as we do not have a time series of aircraft value estimates.

[29] We choose 0.5 as the breakpoint to ease interpretation - as Table 2 shows, 0.5 is only slightly higher than the median LTV (0.49).

[30] In essence, these regressions thus test the triple interaction between our measure of the number of bankrupt buyers, airline profitability and either tranche seniority or LTV.

regression includes tranche and airline fixed effects with standard errors clustered at the tranche level.

As can be seen in Table 14, the coefficient on the interaction term between *Bankrupt Buyers* and profitability is more negative for junior tranches and for tranches with high LTV ratios. In particular, for junior tranches, the impact of profitability on the importance of *Bankrupt Buyers* in determining tranche spreads is approximately ten times larger than the same effect for senior tranches. Having one potential bankrupt buyer and moving from the 25 to the 75 percentiles of airline profitability is associated with a decrease of 89.45 basis points in credit spreads of senior tranches, compared to 265.64 basis points for junior tranches.[31] Likewise, while the interaction term between *Bankrupt Buyers* and profitability is small and not statistically significant for tranches with low LTVs, the effect is much higher and statistically significant for tranches with high LTV.

As a final robustness check, we investigate further the role of the probability of airline bankruptcy. While we find support for the conjecture that the collateral channel is stronger when profitability is lower, our analysis thus far does not account for situations in which an airline's current profitability is low, but its balance sheet is still strong making the airline's default unlikely. To allow for this, we construct a more complete measure of airline health by estimating the probability that an airline will file for Chapter-11 in a given year. We then use airlines' predicted probability of bankruptcy as a more comprehensive measure of the airline's financial health.

Similar to Shumway (2001), we regress the probability of a bankruptcy on lagged values of size, leverage, market-to-book, profitability, the short-term debt to assets ratio, and both year and airline fixed-effects. Our estimated linear probability model (standard errors clustered by airline are reported in parentheses) is:

$$\begin{aligned} Pr(Bankruptcy = 1)_{a,t} &= 0.037 * Size_{a,t-1} + 0.009 * Leverage_{a,t-1} + 0.124 * MtoB_{a,t-1} \\ & \quad\ (0.040) \qquad\qquad\quad (0.323) \qquad\qquad\qquad\quad (0.100) \\ &- 0.787 * Profitability_{a,t-1} + 0.747 * STDebt_{a,t-1} \\ & \quad\ (0.365), \qquad\qquad\qquad\quad (0.238) \\ &+ \mathbf{c}_a \boldsymbol{\eta} + \mathbf{d}_y \boldsymbol{\theta} + \epsilon_{a,t}, \end{aligned} \tag{3}$$

Subscripts indicate airline (a) and transaction date (t), $\mathbf{c}_a$ is a vector of airline fixed-effects, $\mathbf{d}_y$ is

[31] To see the former, note that $(-754.646 \times (0.131 - 0.036) - 620.859 \times 0.301 \times (0.131 - 0.036)) = -89.45$. The latter effect is calculated in an analogous manner.

a vector of year fixed-effects, and $\epsilon_{a,t}$ is the regression residual.

As can be seen, the two significant determinants of bankruptcy are profitability and the ratio of short-term debt to assets. We next calculate imputed bankruptcy probabilities, $Pr(Bankruptcy)$, for each airline-year based on airline characteristics. The last four columns of Table 14 report the coefficients from estimating regressions with interactions between $Bankrupt\,Buyers$ and this $Pr(Bankruptcy)$ measure. As before, we split the sample between junior and senior tranches, and high versus low LTV tranches. Given that $Pr(Bankruptcy)$ is a linear combination of airline characteristics, we do not include airline-level variables in these regressions.

While the estimates based on seniority level are not statistically significant, we find that using LTV to stratify our sample (Columns 7 and 8) yields results consistent with the profitability interaction regressions. We find that for tranches with high loan to value ratios, i.e. those more exposed to default, the effect of $Bankrupt\,Buyers$ on credit spreads increases when the probability of airline bankruptcy is higher. For example, for tranches with LTV>0.5 the incremental effect of one additional bankrupt buyer, evaluated at the 75th percentile of bankruptcy probability (0.22) is 44.9 basis points. In contrast, for tranches with low loan to value (LTV<0.5), the effect of $Bankrupt\,Buyers$ on credit spreads is low even when the probability of default is high, consistent with the protection that the underlying collateral provides for these relatively senior tranches. For example, evaluated at the 75th percentile of bankruptcy probability, the incremental effect of an additional bankrupt buyer is only 18.3 basis points.[32]

To summarize, our results are consistent with the notion that the effect of the collateral channel is larger for more junior and more highly leveraged securities of weaker firms. Even if the airline defaults on its tranche obligations, the most senior claimants will be least exposed to fluctuations in the value of the underlying collateral and hence do not require particularly strong demand for the assets serving as collateral. In contrast, for tranches of lower seniority, profitability plays a much larger role in determining the relation between potential demand for collateral, as proxied by $Bankrupt\,Buyers$, and tranche spread. For these more junior tranches, when the financial health of the firm deteriorates and hence default probabilities go up, being able to find a buyer for the underlying collateral is of crucial importance. Put differently, when profitability is low, junior secured creditors are very much harmed when a large number of potential buyers are experiencing

[32] In calculating these figures we use the total differential taking into account both the level and the interaction term.

financial difficulty and are in bankruptcy.

Finally, we analyze the interaction between the *Bankrupt Buyers* measure and tranche redeployability. Following Shleifer and Vishny (1992), we hypothesize that if assets are more redeployable, potential buyers entering financial distress should have a smaller impact on collateral values and credit spreads. Therefore, the positive relation between *Bankrupt Buyers* and tranche credit spreads should be lower for tranches with more redeployable collateral.

We regress tranche credit spreads on the *Bankrupt Buyers* measure, our measure of tranche redeployability that is based on the number of aircraft, and an interaction between *Bankrupt Buyers* and tranche redeployability. As independent variables we also include our regular set of tranche and airline controls, employing both year and either airline and tranche fixed effects. As can be seen in Table 15, we find that consistent with our hypothesis, the interaction term between *Bankrupt Buyers* and the tranche aircraft redeployability measure is negative and significant. While increases in *Bankrupt Buyers* lead to increased spreads, this effect is weaker in more redeployable tranches. For example, for tranches in the 25th percentile of redeployability, increasing having one bankrupt buyer increases spreads by 76.6 basis points, while in contrast the same effect in tranches at the 75th percentile of redeployability is only 20.3 basis points.

5. Conclusion

Our analysis shows that bankrupt firms impose negative externalities on their non-bankrupt competitors through a collateral channel mechanism in which industry bankruptcies lead to reductions in collateral values of other industry participants. This, in turn, increases the cost of external debt finance across the industry. While our analysis focuses on one particular industry, the collateral channel has broader, economy-wide implications. Indeed, the collateral channel should be viewed as a particular form of financial accelerator in which frictions in raising external finance amplify and propagate industry downturns. Following a negative shock, a fraction of firms enter bankruptcy and sell part of their assets. As a result, collateral values drop industry wide, increasing the cost of external finance, magnifying the shock further. Recent events in the ongoing financial crisis of 2007-2009 suggest that bankruptcy induced contagion through collateral shocks are of crucial importance in magnifying shocks to the economy at large. If such bankruptcy-induced externalities are sufficiently large, the collateral channel may ultimately result in downward spirals – bankruptcies lead to declines in collateral values and capital availability industry-wide, thereby inducing even more bankruptcies.

Appendix A. Constructing Redeployability and Bankruptcy Measures

In this appendix we provide more detail regarding the construction of the redeployability variables and the bankruptcy variables used in the analysis.

As in Benmelech and Bergman (2008 and 2009) and Gavazza (2008), we measure the redeployability of aircrafts by exploiting aircraft model heterogeneity. In order to reduce costs associated with operating different aircraft types, airlines tend to operate a limited number of aircraft models. Potential secondary market buyers of any given type of aircraft, therefore, are likely to be airlines already operating the same type of aircraft. Thus, redeployability is proxied by the number of potential buyers and the 'popularity' of an aircraft model type.

Using the Ascend CASE database, we construct two redeployability measures in the following manner. We first construct annual redeployability measures for each aircraft type. For every aircraft type and sample-year we compute 1) the number of non-bankrupt operators flying that aircraft model type; and 2) the number of aircraft of that type used by non-bankrupt operators. This process yields two redeployability measures for each aircraft-type and each sample-year. To construct the redeployability measures for a portfolio of aircraft serving as collateral for a particular tranche, we aggregate the aircraft-type redeployability measures across all aircraft in the portfolio. Specifically, we define the redeployability of the collateral-portfolio to be the weighted average of the redeployability index corresponding to each of the aircraft in the portfolio. The two measures are given by:

$$Redeployability_{i,t}^{aircraft} = \sum_{s}^{S} \omega_{i,t,s}(Redeployability_{s,t}^{aircraft})$$

$$Redeployability_{i,t}^{operators} = \sum_{s}^{S} \omega_{i,t,s}(Redeployability_{s,t}^{operators})$$

where i is a tranche, t is sample year, s denotes an aircraft type, and $\omega_{i,t,s}$ is defined as

$$\omega_{i,t,s} = number_{i,t,s} \times seats_s \Bigg/ \sum_{s}^{S} number_{i,t,s} \times seats_s$$

We use the number of seats in an aircraft model as a proxy for its size (and value) in our weighted average calculations.

We construct two measures of shocks to collateral driven by airlines entering bankruptcy. For each aircraft type and calendar day in our sample we calculate (1) the number of airlines operating that particular model type which are in bankruptcy; and (2) the number of aircraft of that particular type which are operated by airlines in bankruptcy.[33] Since changes in aircraft ownership are relatively infrequent, ownership information of aircraft is updated at a yearly rather than daily frequency. However, the two measures may change at a daily frequency due to airlines entering or exiting bankruptcy.

[33] We calculate these measures using beginning and end dates of airline bankruptcies from SDC Platinum.

As for the redeployability measures described above, to construct the bankruptcy measures for a portfolio of aircraft serving as collateral for a particular tranche, we aggregate the aircraft-type measures across all aircraft in the portfolio. To do so, we calculate the weighted average of the bankrupt buyer measure corresponding to each of the aircraft in the portfolio. Specifically, we calculate:

$$BankruptBuyers_{i,t} = \sum_{s}^{S} \omega_{i,t,s}(BankruptBuyers_{s,t})$$

$$BankruptAircraft_{i,t} = \sum_{s}^{S} \omega_{i,t,s}(BankruptAircraft_{s,t})$$

where i is a tranche, t is a sample date, s denotes an aircraft type, and $\omega_{i,t,s}$ is a seat-based weighting scheme defined as above. Thus, for each tranche collateral pool, this process produces two measures of bankruptcy induced collateral shocks for each trading day.

Figure A1 provides a timeline of airline bankruptcies in the United States over the sample period. The figure displays the timeline of the bankruptcies (on the horizontal axis) against the number of aircraft operated by the airline on the date the airline filed for bankruptcy. Fifteen airlines went bankrupt over the sample period, with three of them – TWA, Hawaiian, and US Airways – going through bankruptcy twice. The average (median) duration of an airline bankruptcy in our sample is 1.51 (1.35) years. As can be seen from the figure, the recession that began in March 2001 and the subsequent September 11th, 2001 attacks mark a period of increased bankruptcy activity. Furthermore, several of the airlines that went bankrupt in the post 9/11 periods were very large (e.g. United, Delta, Northwest, and US Airways) and involved a large number of aircraft operated by bankrupt airlines.

Finally, Figure A2 presents the total number of aircraft operated by bankrupt US airlines over the sample period. The figure shows how following the recession that started September 11th 2001 the number of aircraft of bankrupt airlines increases dramatically to a maximum of 1,706 aircraft in 2005 when ATA, Delta, Northwest, United, and US Airways were all in chapter-11. This number decreases as United exists from bankruptcy in February 2006, and falls further in 2007 as both Northwest and Delta exit bankruptcy in 2007.

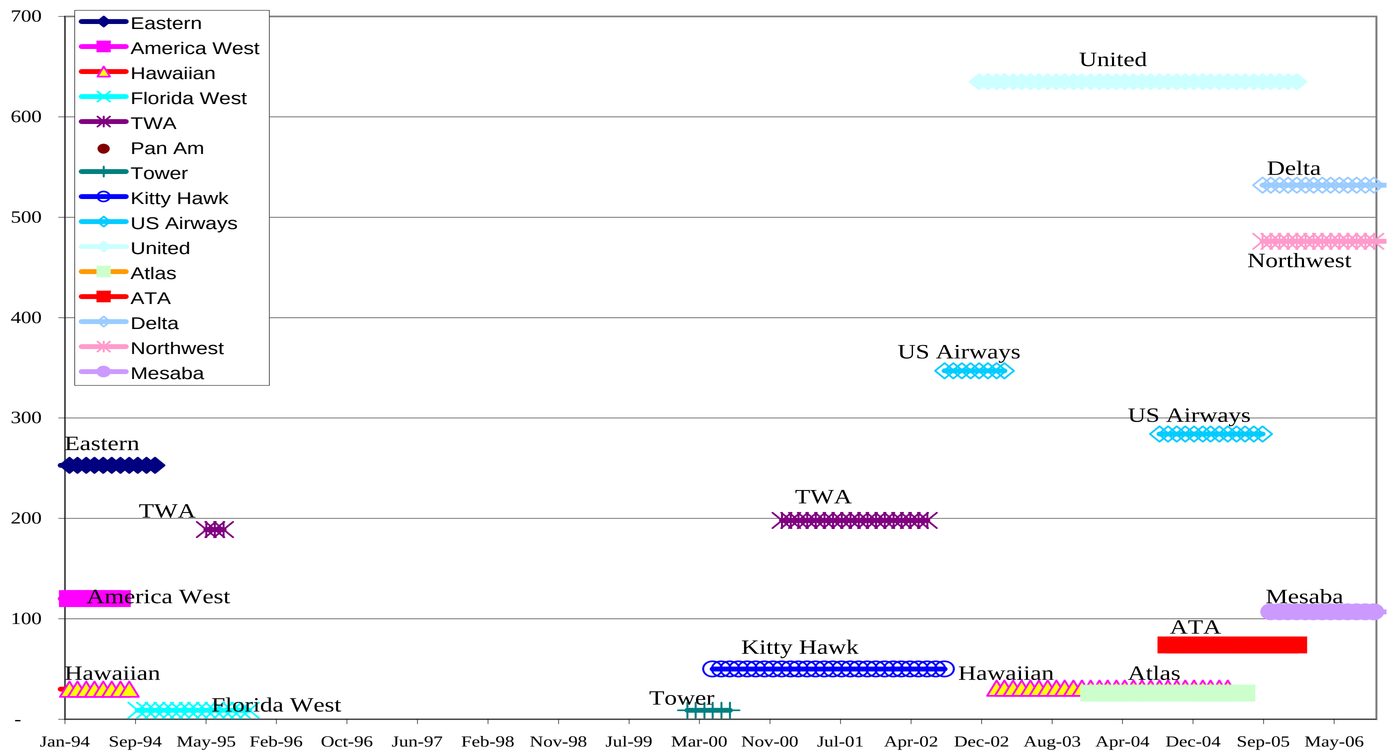

FIGURE A1: Timeline of airline bankruptcies in the U.S. 1994-2006. Airline bankruptcy dates are obtained from SDC Platinum.

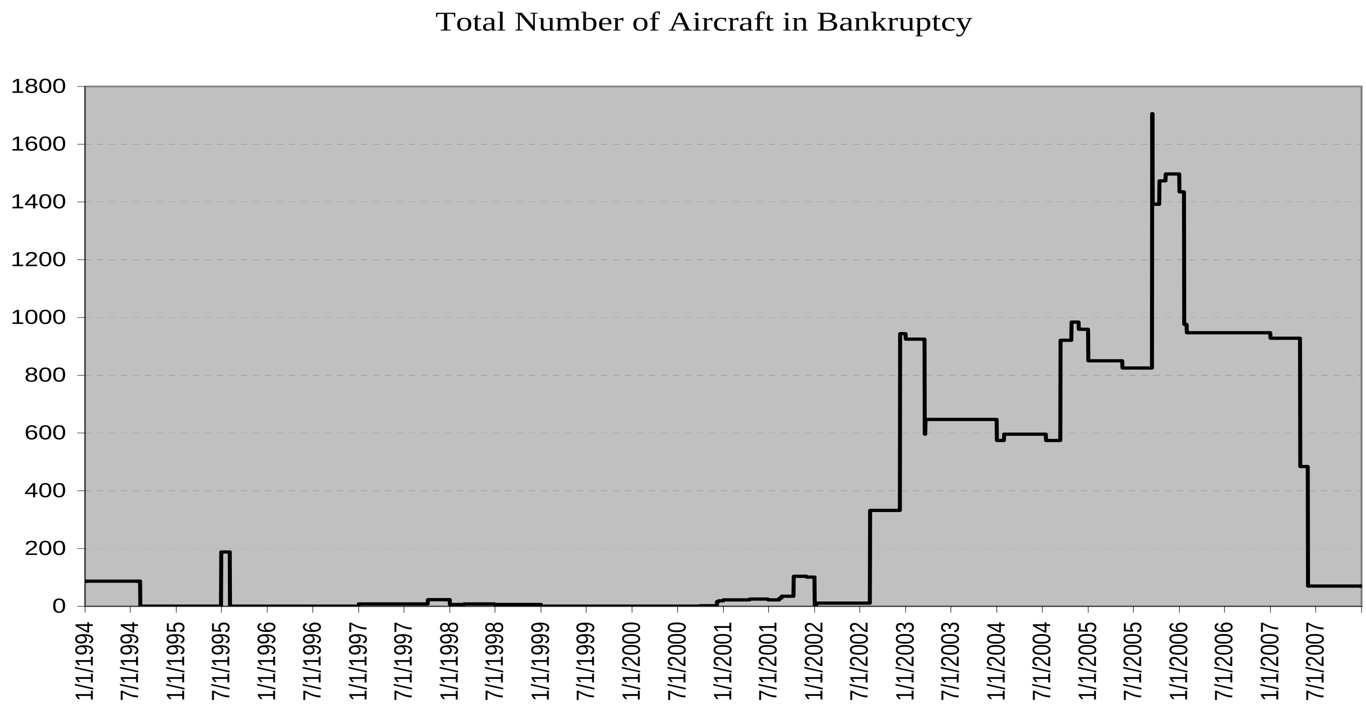

FIGURE A2: Total number of aircraft operated by bankrupt airlines in the U.S. 1994-2007. Airline bankruptcy dates are obtained from SDC Platinum. Fleet data is obtained from the Ascend CASE database.

Appendix B: Variable description and construction

For reference, the following is a list of variables used in the paper, their sources, and a brief description of how each variable is constructed.

1. *Amortizing*: Takes the value of 1 if the tranche is amortized (Source: SDC and Issue Prospectus from EDGARPlus(R)).
2. *Bankrupt Assets/Total Assets*: The aggregate book asset value of airlines with current filings under Chapter-11 divided by the aggregate book asset value of all airlines in the U.S. (Source: SDC and Bureau of Transportation Statistics).
3. *Bankruptcy dummy*: Takes the value of 1 if the airline has filed for bankruptcy protection during a particular year, and 0 otherwise. (Source: SDC).
4. *Call Provision*: Takes the value of 1 if the tranche is callable. (Source: SDC).
5. *Fuel Price*: The barrel price of Kerosene jet fuel in $dollars. (Source: the Energy Information Administration website).
6. *Healthy Assets/Total Assets*: The aggregate book asset value of non-bankrupt airlines divided by the aggregate book asset value of all airlines in the U.S. (Source: SDC and Bureau of Transportation Statistics).
7. *Leverage*: The firm's total current liabilities+long-term debt [Compustat Annual Items 9+34+84] all divided by book value of assets [Compustat Annual Item 6]. (Source: Compustat).
8. *Liquidity Facility*: Takes the value of 1 if the tranche has a liquidity facility enhancement. (Source: Issue Prospectus from EDGARPlus(R)).
9. *LTV*: The tranche initial cumulative loan-to-value (Source: Issue Prospectus from EDGARPlus(R)).
10. *Market-to-book*: The airline's market value of equity [Compustat Annual Items 24*25] + book value of assets [Compustat Annual Item 6] minus the book value of equity [Compustat Annual Item 60] all over book value of assets [Compustat Annual Item 6]. (Source: Compustat).
11. *Number Bankrupt*: The number of airlines with current filings under Chapter-11 . (Source: SDC).
12. *Number Bankrupt/Total*: The number of airlines with current filings under Chapter-11 divided by the total number of airlines in the U.S. (Source: SDC and Bureau of Transportation Statistics).
13. *Number Healthy*: The number of non-bankrupt airlines. (Source: SDC).
14. *Number Healthy/Total*: The number of non-bankrupt airlines divided by the total number of airlines in the U.S. (Source: SDC and Bureau of Transportation Statistics).
15. *Post 9/11 dummy*: Takes the value of 1 for transaction dates after September-11, 2001.
16. *Profitability*: Earnings [Compustat Annual Item 13] over total assets [Compustat Annual Item 6]. (Source: Compustat).

17. *Seniority*: Takes the value of 1 (senior) 2, 3, and 4 (junior). (Source: SDC and Issue Prospectus from EDGARPlus(R)).

18. *Size*: The logarithm of the airline's total book assets (Source: Compustat).

19. *Spread*: The tranche credit spread (in basis points) over a maturity-matched Treasury. (Source: Mergent).

20. *Term-to-Maturity*: The tranche term-to-maturity (in years). (SDC and Mergent).

21. *Tranche Size*: The logarithm of the tranche issue size (in millions). (SDC).

Appendix C. Additional Robustness Tests

Table C1
Bankruptcy and Collateral: Controlling for Buyers and Sellers Effects

The table presents coefficient estimates and standard errors in parentheses for credit spread regressions. Columns 1-4 split the sample into transactions made by Life Insurance firms and Property & Casualty firms. Columns 5-8 include vendor fixed-effects when this information is available. All regressions include an intercept, yield curve and default spread controls (Short-rate, Term-spread and Default-spread) (not reported). Standard errors are calculated by clustering at the tranche level. Variable definitions are provided in Appendix B. a, b and c denote statistical significance at the 1%, 5%, and 10% levels, respectively.

Healthy Assets/Total Assets	0.925	0.905	0.917	0.940	0.033	0.881	1.000

Table 3:
Bankrupt Buyers and Bankrupt Aircraft Measures

This table provides descriptive statistics for the bankrupt buyers and bankrupt aircraft measures used in the empirical analysis. Panel A displays statistics for the entire sample, while Panel B and Panel C provide the statistics for different sample periods for each of the measures. Details on the construction of the Bankrupt Buyers and Bankrupt Aircraft measures are provided in Appendix B.

Panel A: Bankrupt Buyers and Number of Aircraft in Bankruptcy

	Mean	25th Percentile	Median	75th Percentile	Standard Deviation	Min	Max
Bankrupt buyers	0.809	0.0	0.269	1.571	1.027	0.0	5.0
Bankrupt aircraft	43.860	0.0	2.628	86.177	63.275	0.0	311.0

Panel B: Bankrupt Buyers over Time

Year	Mean	25th Percentile	Median	75th Percentile	Standard Deviation	Min	Max	Observations
1994-2000	0.013	0.0	0.0	0.0	0.077	0.0	1.0	4,814
2001	0.324	0.0	0.244	0.528	0.348	0.0	1.0	3,421
2002	0.578	0.0	0.396	1.0	0.648	0.0	3.0	3,056
2003	1.411	0.608	1.725	2.161	0.872	0.0	3.0	2,937
2004	1.604	0.533	1.732	2.299	1.171	0.0	4.0	2,497
2005	2.058	0.105	2.167	3.336	1.483	0.0	5.0	1,826

Panel C: Bankrupt Aircraft over Time

Year	Mean	25th Percentile	Median	75th Percentile	Standard Deviation	Min	Max	Observations
1994-2000	0.227	0.0	0.0	0.0	1.859	0.0	57	4,814
2001	3.042	0.0	1.461	5.751	3.817	0.0	17	3,421
2002	23.832	0.0	2.388	52.851	39.208	0.0	274	3,056
2003	93.286	31.529	111.585	128.242	61.598	0.0	273	2,937
2004	91.445	13.0	96.509	118.132	70.884	0.0	282	2,497
2005	110.021	3.206	117.976	182.282	83.939	0.0	311	1,826
2006	63.323	0.0	73.0	93.846	54.236	0.0	264	2,834
2007	14.885	0.0	0.0	8.947	34.126	0.0	181	1,003

Table 4:
Bankruptcy, Bankrupt Buyers and Tranche Credit Spreads Univariate Analysis

This table provides univariate analysis of tranche credit spreads: Panel A segments credit spreads of tranches of non-bankrupt and bankrupt airlines, Panel B focuses on non-bankrupt airlines and compares tranche credit spreads of tranches with a positive bankrupt buyer measure and those with a bankrupt buyers measure equal to zero, while Panel C stratifies the analysis in Panel B by tranche seniority, and reports means and t-statistics for t-tests on equal means using standard errors that are clustered at the tranche level.

Panel A: Tranche Credit Spreads of Bankrupt and Non-Bankrupt Airlines: Summary Statistics

	Mean	10th Percentile	25th Percentile	Median	75th Percentile	Standard Deviation	Observations
Bankrupt airlines	531.7	135.1	188.4	317.4	592.4	649.9	1,011
Non bankrupt airlines	276.1	94.2	152.6	226.1	322.7	273.3	17,316
Difference	255.6						
T-test for equal means	(2.81)						

Panel B: Tranche Credit Spreads of Non-Bankrupt Airlines: Summary Statistics

	Mean	10th Percentile	25th Percentile	Median	75th Percentile	Standard Deviation	Observations
Bankrupt buyers>0	339.0	135.9	197.7	271.7	363.4	336.1	8,992
No bankrupt buyers	208.0	75.4	129.4	177.1	253.3	156.3	8,324
Difference	131.0						
T-test for equal means	(7.48)						

Panel C: Tranche Credit Spreads of Non-Bankrupt Airlines and Seniority: Means and T-tests

	Senior 1	2	3	Junior 4	Diff (2-1) (T-test)	Diff (3-1) (T-test)	Diff (4-1) (T-test)
Bankrupt buyers>0	302.5	419.2	474.9	1444.9	116.7	172.47	1142.5
(Observations)	(6,755)	(1,613)	(590)	(34)	(3.79)	(2.81)	(7.54)
No bankrupt buyers	207.5	223.7	177.5	332.0	16.3	30.03	124.5
(Observations)	(6,481)	(1,187)	(625)	(31)	(0.51)	(1.86)	(4.77)
Difference	95.0	195.5	297.4	1112.9			
T-test for equal means	(5.70)	(4.08)	(5.15)	(6.79)			

Table 5:
Bankruptcy and Collateral

The table presents coefficient estimates and standard errors in parentheses for credit spread regressions. Panel A uses the *Bankrupt Buyers* measure while Panel B uses the *Bankrupt Aircraft* measure. For each specification, Panel C of the table provides estimates of the magnitude of the economic effect of either a one standard deviation move or a 25th to 75th percentile movement in the *Bankrupt Buyers* and *Bankrupt Aircraft* measures on tranche credit spread. All regressions include an intercept, yield curve, and default spread controls (Short-rate, Term-spread and Default-spread), and year fixed-effects (not reported). Standard errors are calculated by clustering at the tranche level. Variable definitions are provided in Appendix B. a, b and c denote statistical significance at the 1%, 5%, and 10% levels, respectively.

Panel A: Bankrupt Buyers

Dependent Variable=	Tranche Spread	Tranche Spread	Tranche Spread	Tranche Spread	Tranche Spread	Tranche Spread
Bankrupt Buyers	246.491 a	151.619 a	106.162 a	93.614 a	119.030 a	118.937 a

Table 9:
The Collateral Channel and Tranche Fleet

The table presents coefficient estimates and standard errors in parentheses for credit spread regressions. All regressions include an intercept, yield curve, and default spread controls (Short-rate, Term-spread and Default-spread), and tranche fixed-effects (not reported). Columns 1 and 2 also include aircraft model×year fixed effects. Column 3 and 4 focus on aircraft manufactured by either Airbus and Boeing (column 3) or Boeing only (column 4). The last two columns of the table also includes a dummy variable for wide-body aircraft interacted with month-year fixed effects. Tranche controls are not included in the explanatory variables as they are absorbed by the tranche fixed-effects. Standard errors are calculated by clustering at the tranche level. Variable definitions are provided in Appendix B. a, and b denote statistical significance at the 1%, and 5% levels, respectively.

Table 12:
Bankruptcy Collateral and Investment Grade

The table presents coefficient estimates and standard errors in parentheses for credit spread regressions. Regressions are estimated separately for Buy vs. Sell transactions. All regressions include an intercept, yield curve, and default spread controls (Short-rate, Term-spread and Default-spread), as well as airline and year fixed-effects (not reported). The first two columns compare buy vs. sell transactions of tranches with Moody's investment grade credit ratings. Columns 3 and 4 compare buy vs. sell transactions of tranches with Moody's ratings that are between Aaa and Aa3. Columns 5 and 6 compare buy vs. sell transactions of tranches with Aaa Moody's credit rating. The last two columns compare buy vs. sell transactions of tranches with Moody's investment grade credit ratings for the 1994-2005 period, excluding the years 2006 and 2007. Standard errors are calculated by clustering at the tranche level. Variable definitions are provided in Appendix B. a, b and c denote statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 13:
Bankruptcy, Collateral, Tranche Seniority and LTV

The table presents coefficient estimates and standard errors in parentheses for credit spread regressions. Regressions are estimated separately for senior and junior tranches (columns 3 and 4), and for tranches with loan-to-value lower than 0.5 (column 7) and higher than 0.5 (column 8). All regressions include an intercept, yield curve, and default spread controls (Short-rate, Term-spread and Default-spread), and year fixed-effects (not reported). Columns 1 and 5 include airline fixed-effects, and columns 2, 3, 6, 7 and 8 include tranche-fixed effects. Standard errors are calculated by clustering at the tranche level. Variable definitions are provided in Appendix B. a, b and c denote statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 14:
The Collateral Channel and Airline's Financial Strength

The table presents coefficient estimates and standard errors in parentheses for credit spread regressions. Regressions are estimated separately based on seniority (columns 1 vs. 2, and columns 5 vs. 8), and loan-to-value (columns 3 vs. 4, and columns 7 vs. 8). All regressions include an intercept, yield curve, and default spread controls (Short-rate, Term-spread and Default-spread), as well as tranche and year fixed-effects (not reported). Standard errors are calculated by clustering at the tranche level. Variable definitions are provided in Appendix B. a, b and c denote statistical significance at the 1%, 5%, and 10% levels, respectively.
