Transition to FDI Openness: Reconciling Theory and Evidence
Ellen R. McGrattan
NBER Working Paper No. 16774
February 2011
JEL No. E01,E2,F21,F23,F36,F41

ABSTRACT

Empirical studies quantifying the economic effects of increased foreign direct investment (FDI) have not provided conclusive evidence that they are positive, as theory predicts. This paper shows that the lack of empirical evidence is consistent with theory if countries are in transition to FDI openness. Anticipated welfare gains lead to temporary declines in domestic investment and employment. Also, growth measures miss some intangible FDI, which is expensed from company profits. The reconciliation of theory and evidence is accomplished with a multicountry dynamic general equilibrium model parameterized with data from a sample of 104 countries during 1980-2005. Although no systematic benefits of FDI openness are found, the model demonstrates that the eventual gains in growth and welfare can be huge, especially for small countries.

1. Introduction

Theory predicts that the economic effects in a host country of increased foreign direct investment (FDI) are positive, but empirical studies have been unable to provide conclusive evidence consistent with that prediction. For example, Kose, Prasad, Rogoff, and Wei's (2009) survey of empirical cross-country studies reports that only one finds a positive impact of FDI on economic growth. Here, I show that these inconclusive findings do not contradict theory, but in fact are to be expected when countries are in transition to capital market openness.

I show this by closely examining such a transition period in a multicountry dynamic general equilibrium model. In the model, countries initially face restrictions on foreign capital investments—both FDI and portfolio—that are gradually relaxed. Building on my 2010 work with Prescott, I allow for a large number of integrated economies with multinational companies investing at home in technology capital that can also be used nonrivalrously in their subsidiaries abroad. As a country's restrictions on the investment of foreign capital begin to be relaxed, the model predicts per capita GDP and employment initially both fall below historical trends and do not recover until the restrictions are sufficiently relaxed.

GDP and employment decline for two reasons. One is that when such a relaxation is expected, households increase consumption and leisure in expectation of higher permanent income, thereby reducing domestic investment and labor. This income effect occurs because relaxed restrictions on future FDI imply a higher effective level of total factor productivity (TFP). The other reason for GDP declines is a measurement issue. Part of the increased FDI will be expensed intangible investment and not counted as part of corporate profits, so will not be captured in measured GDP. Theory predicts that intangible investments are abnormally high while barriers to FDI are being removed; that implies a negative correlation between FDI investment and host country GDP.¹

But, again, theory also predicts positive effects in the host country from increased FDI.

¹ Thus, it appears that capital is flowing in the wrong direction—namely, to countries with slow or negative growth—which is consistent with observations but puzzling for standard neoclassical theory that abstracts from intangible investment. See Gourinchas and Jeanne (2007).

GDP and employment eventually rise above trend once the transition period has passed. And, if there are no constraints on international borrowing and lending, consumption rises as soon as relaxed restrictions are announced. If there are borrowing constraints that limit portfolio investments, the rise in consumption is more gradual. But, in either case, welfare in the host country is higher.

I investigate the transition path to FDI openness in two versions of the model: a simple two-country version and a more realistically parameterized 104-country version.

The simple version of the model allows me to qualitatively describe, fairly precisely, the transition paths of various economic variables in countries of different sizes, where *size* is defined by population and level of technology. The *transition* is defined basically as the period between the time an announcement is made that FDI restrictions are to be relaxed at a specified future date and the time the restrictions are actually relaxed. I consider equilibrium paths with and without coincident restrictions on portfolio investments.

The more realistic version allows me, first, to conduct the standard empirical analysis of quantifying the impact of FDI on economic growth. Countries are included in the analysis if they have complete data on inward FDI, net portfolio investment, GDP, and populations over the period 1980–2005. Observations on inward FDI are used to parameterize time paths of country openness parameters, which are policy parameters determining the inflow of FDI. Observations on net portfolio investment are used to parameterize borrowing constraints on portfolio flows. The model is simulated and growth in GDP per capita computed. The result of this 104-country analysis is consistent with that in the literature. Using standard analysis, the model finds no evidence of large positive effects from FDI. The amount of FDI in a country is not positively correlated with growth in GDP or TFP and not statistically significant in a standard cross-country growth regression.

Yet this same model does predict large positive effects to FDI openness, in terms of both growth and welfare. I demonstrate this effect by conducting a counterfactual experiment. I recompute equilibria for the 104-country version of the model, relaxing capital market restrictions almost completely for one country at a time, and estimate per

capita growth in GDP and the welfare gain to each country from doing that. I find increases in annual growth rates in the range of 0 to 7 percentage points and welfare gains that are equivalent to consumption increases in the range of 4 percent to 460 percent. The gains in growth and welfare are both inversely related to country size.

A methodological contribution of my work here is the computation of equilibria in a dynamic general equilibrium model with a large number of integrated countries. Multinationals in the model choose investments in tangible capital, plant-specific intangible capital, and technology capital, both at home and abroad. With many countries and different types of capital, the problem is tractable only if the computations are divided across parallel processors. An initial guess for all prices and transfers is distributed across processors, and equilibrium quantities are computed and then passed back to the main processor. Prices and transfers are updated, and the algorithm continues until a fixed point is found.

My work here is related to the literature that quantifies the impact of capital account liberalization. Most of the theoretical work in this literature abstracts from FDI flows, focusing instead on portfolio investment and the integration of countries with different financial systems or levels of capital at different stages of financial development.² Here, foreign direct and portfolio investment are both essential: lowering barriers to FDI increases the effective production sets for firms, and lowering barriers to portfolio investment allows households to better smooth consumption.

Related work that does explore the quantitative impact of FDI openness finds large output and welfare gains. Burstein and Monge-Naranjo (2009) estimate the gains of real-locating managerial know-how abroad using a span-of-control model as in Lucas (1978). Ramondo (2010) estimates the gains of lower barriers to FDI in Eaton and Kortum's (2002) model without trade, but with multinational production. Ramondo and Rodríguez-Clare (2010a, 2010b) consider both trade and FDI in the Eaton-Kortum framework.³ The results in these studies are the motivation for the current study, since they all conclude that the

² Recent examples include Gourinchas and Jeanne (2006), Caballero, Farhi, and Gourinchas (2008), Mendoza, Quadrini, and Ríos-Rull (2009), and Aoki, Benigno, and Kiyotaki (2009).

³ In McGrattan and Prescott (2009), we concluded that there are large *potential* gains to FDI openness based on several numerical examples, but we did not calibrate the model to actual data.

output and welfare gains to FDI openness are large, whereas empirical studies have found little conclusive evidence of positive economic effects.⁴

Section 2 lays out the multicountry general equilibrium model used in the analysis. Section 3 is a set of propositions that qualitatively characterize the transition path in a two-country version of the model. Section 4 is an application of the model to actual cross-country data and so quantifies that transition path as well as the overall output and welfare gains. Section 5 concludes.

2. Model

In this section, I describe a multicountry general equilibrium model that builds on McGrattan and Prescott (2009, 2010). I describe first the problem solved by multinational companies and then the problems faced by households. Finally, I define a competitive equilibrium for the model economy and describe how to match up national accounting statistics with their model counterparts.

2.1. Multinationals

Multinational companies from country j operating in country i produce output Y_{it}^j in period t ,

$$Y_{it}^j = A_{it}\sigma_{it} \left(N_{it}M_t^j\right)^\phi \left(Z_{it}^j\right)^{1-\phi},$$

with *technology capital* M_t^j and a composite of country-specific inputs denoted by Z_{it}^j .⁵ The parameter $\phi \geq 0$ governs technology capital's share of income. Technology capital is accumulated know-how from investments in such things as research and development (R&D), brands, and organizational capital that can be used in as many locations as firms choose, both at home and abroad. The total number of locations available in country i in period t is N_{it} , and firms take this as given in solving their optimization problem. Since technology capital can be used simultaneously in multiple locations, it is not indexed by i .

⁴ A recent empirical literature has begun to focus on countries that have passed certain thresholds when relaxing capital restrictions. See, for example, the work of Kose, Prasad, and Taylor (forthcoming).

⁵ For a micro-foundation of this aggregate production function, see the work of McGrattan and Prescott (2009).

The span of control of this organizational capital is limited because countries are assumed to have a fixed number of production locations.

Country i 's total factor productivity in t is denoted by A_{it} . For multinationals incorporated outside i , the effective level of productivity if they operate in i is $A_i\sigma_i$, where σ_i is the degree of openness of country i to FDI. A value for σ_i of 1 implies that the country is totally open—or that domestic and foreign firms have the same opportunities. A value of less than 1 implies that domestic and foreign firms are not treated equally by the host country. In particular, with $\sigma_i < 1$, investment by foreign firms entails extra costs, and these costs have the same effect as if the foreign firms had lower TFP than domestic firms.

The composite capital-labor input in country i is modeled as a Cobb-Douglas technology,

$$Z_i^j = \left(K_{T,i}^j\right)^{\alpha_T} \left(K_{I,i}^j\right)^{\alpha_I} \left(L_i^j\right)^{1-\alpha_T-\alpha_I}, \quad (2.1)$$

with inputs of tangible capital $K_{T,i}^j$, plant-specific intangible capital $K_{I,i}^j$, and labor L_i^j . This specification of technology implies that multinationals use two types of intangible capital, one that is plant-specific and one that is not.

The stand-in multinational company from country j maximizes the present value of the stream of after-tax dividends:

$$\max (1 - \tau_d) \sum_t p_t D_t^j, \quad (2.2)$$

where τ_d is the tax rate on dividends and the sum of dividends across all operations in all countries indexed by i is given by $D_t^j = \sum_i D_{it}^j$, with

$$D_{it}^j = (1 - \tau_{pi}) \left(Y_{it}^j - W_{it} L_{it}^j - \delta_T K_{T,it}^j - X_{I,it}^j - \chi_i^j X_{M,t}^j \right) - K_{T,i,t+1}^j + K_{T,it}^j, \quad (2.3)$$

where $\chi_i^j = 1$ if $i = j$ and 0 otherwise, δ_T is the depreciation rate of tangible capital, $X_{I,i}^j$ is investment in plant-specific intangible capital which is split among the locations in country i that j operates, and X_M^j is the technology capital investment of multinational j used in all locations in which j operates.⁶ The multinational takes as given sequences of prices p_t and wages W_{it} . The same wage rate is paid by all multinationals operating in i .

⁶ To avoid having to account for clientele effects, I assume that all dividends are taxed at the same rate.

Dividends for the multinational companies (indexed by j) are equal to worldwide after-tax profits less net investment of tangible capital, $\sum_i (K_{T,i,t+1}^j - K_{T,it}^j)$. Taxable profits are equal to sales less expenses, where the expenses are wage payments, tangible depreciation, and expensed investments on plant-specific intangible capital and technology capital. Taxable profits in country i are taxed at rate τ_{pi} . The capital stocks of the multinational in the next period are given by

$$K_{T,i,t+1}^j = (1 - \delta_T) K_{T,it}^j + X_{T,it}^j \quad (2.4)$$

$$K_{I,i,t+1}^j = (1 - \delta_I) K_{I,it}^j + X_{I,it}^j \quad (2.5)$$

$$M_{t+1}^j = (1 - \delta_M) M_t^j + X_{M,t}^j, \quad (2.6)$$

where δ_I and δ_M are depreciation rates of plant-specific intangible capital and technology capital, respectively.

2.2. Households

In each period t , households in country i choose how much to consume C_{it} , how much total labor to supply L_{it} , and how much to borrow from abroad, $B_{i,t+1} - B_{i,t}$. Without loss of generality, I assume that households in i own all of the equity shares of multinationals incorporated in i ; thus, foreign borrowing and lending residually determine their net portfolio income. The maximization problem for the stand-in household is to

$$\max_{\{C_{it}, L_{it}, B_{i,t+1}\}} \sum_t \beta^t N_{it} [\log(C_{it}/N_{it}) + \psi \log(1 - L_{it}/N_{it})]$$

subject to

$$\sum_t p_t [C_{it} + B_{i,t+1} - B_{it}] \leq \sum_t p_t [(1 - \tau_{li}) W_{it} L_{it} + (1 - \tau_d) D_t^i + r_{bt} B_{it} + \kappa_{it}],$$

where $\beta \in (0, 1)$ is the discount factor, $\psi \geq 0$ is a preference parameter governing disutility of labor, and the total population in i is assumed to be proportional to the total number of locations N_{it} . Without loss of generality, I assume a constant of proportionality of 1 between the number of people and the number of production locations within a country.

Households take as given the sequence of returns on portfolio income r_{bt} , wage rates W_{it} , prices p_t , and government transfers κ_{it} . Labor is not mobile across countries but can be supplied to domestic or foreign companies. Taxes are levied on labor at rate τ_{li} .⁷

2.3. Competitive Equilibrium

The competitive equilibrium in this model is defined as a set of prices $\{p_t, r_{bt}, W_{it}\}$ and quantities $\{D_{it}^j, Y_{it}^j, K_{T,it}^j, K_{I,it}^j, M_t^j, L_{it}^j, L_{it}, C_{it}, B_{it}, X_{T,it}^j, X_{I,it}^j, X_{M,t}^j\}$ that are consistent with the maximization problems of multinationals and households. In addition, markets must clear. The market-clearing condition for the labor market in each country i is that

$$\sum_j L_{it}^j = L_{it}.$$

The market-clearing condition for financial assets is that

$$\sum_i B_{it} = 0.$$

The market-clearing condition for goods is that

$$\sum_i \left\{ C_{it} + \sum_j \left(X_{T,it}^j + X_{I,it}^j \right) + X_{M,t}^i \right\} = \sum_{i,j} Y_{it}^j.$$

These conditions, along with the household budget constraints above, imply that government transfers in country i satisfy this:

$$\kappa_{it} = \tau_{li} W_{it} L_{it} + \tau_d D_t^i + \tau_{pi} \left\{ \sum_j \left(Y_{it}^j - \delta_T K_{T,it}^j - X_{I,it}^j \right) - W_{it} L_{it} - X_{M,t}^i \right\}.$$

2.4. Accounting Measures

Before deriving properties of the competitive equilibrium, I need to describe how to construct the national accounting statistics for the model. The measures I use are those used as inputs in the empirical studies surveyed by Kose, Prasad, Rogoff, and Wei (2009).

⁷ Since tax rates are constant, I here combine taxes on consumption and labor into the labor wedge τ_{li} .

Gross domestic product (GDP) for country i in period t is given by

$$\text{GDP}_{it} = C_{it} + \sum_j X_{T,it}^j + NX_{it}, \quad (2.7)$$

where NX_i is net exports of goods and services by country i . Consumption and investment include both private and public expenditures. Intangible investments are expensed and therefore not included in the measure of GDP. In other words, GDP is not a measure of total output. GDP is lower because some investments are expensed.

To see this, consider a second way of calculating GDP: namely, to add up all domestic incomes. Specifically, if we sum compensation of households $W_i L_i$, total before-tax profits of businesses operating in i , $Y_i - W_i L_i - \sum_j (\delta_T K_{T,i}^j + X_{I,i}^j) - X_M^i$, and tangible depreciation $\sum_j \delta_T K_{T,i}^j$, then we have GDP from the income side:

$$\text{GDP}_{it} = Y_{it} - X_{M,t}^i - \sum_j X_{I,it}^j. \quad (2.8)$$

This sum has to be equal to the sum of products in (2.7). From (2.7) and (2.8), it is easy to calculate net exports as total output produced in country i less the sum of consumption and all investments.

Next, add flows to and from other countries. Gross national product (GNP) is the sum of GDP and net factor income from abroad. Net factor receipts (NFR) are the sum of the FDI income of multinationals and the portfolio income of households:⁸

$$\text{NFR}_{it} = \sum_{l \neq i} \{D_{lt}^i + K_{T,l,t+1}^i - K_{T,lt}^i\} + \max(r_{bt} B_{it}, 0). \quad (2.9)$$

Analogously, net factor payments (NFP) from i to the rest of the world are the sum of FDI income of foreign affiliates in i sent back to foreign parents and portfolio incomes of country i that are sent to investors outside of i :

$$\text{NFP}_{it} = \sum_{l \neq i} \{D_{it}^l + K_{T,i,t+1}^l - K_{T,it}^l\} + \max(-r_{bt} B_{it}, 0). \quad (2.10)$$

⁸ Equity in overseas operations is categorized as capital from direct investment when the ownership exceeds 10 percent. Otherwise, it is categorized as capital from portfolio investment.

Adding net factor income to net exports and to GDP gives the current account (CA) and GNP:

$$CA_{it} = NX_{it} + NFR_{it} - NFP_{it} \quad (2.11)$$

$$GNP_{it} = GDP_{it} + NFR_{it} - NFP_{it}. \quad (2.12)$$

In the balance of payments, the current account must equal the financial account, which is the sum of new acquisitions abroad. For the model, the financial account for country i is

$$FA_{it} = \sum_{l \neq i} (K_{T,l,t+1}^i - K_{T,lt}^i) - \sum_{l \neq i} (K_{T,i,t+1}^l - K_{T,it}^l) + (B_{it+1} - B_{it}), \quad (2.13)$$

where the first term is net FDI by multinationals from i abroad, the second term is the (negative) of net new investment by foreigners operating in i , and the third term is new portfolio acquisitions by households from i . Empirical studies report regressions of per capita growth of GDP on FDI (or FDI relative to some measure of aggregate output), controlling for changes in other variables. The right-side variable of those regressions is the second term of (2.13).

3. A Qualitative Assessment

Now I describe, qualitatively, the equilibrium path of this economy as capital markets open. In order to make precise predictions about these paths in transition, I consider two countries, differing only in size, that agree to open their capital markets to each other at a prespecified date in the future. I examine how common measures of economic performance change between the time the liberalization is announced and the time it actually occurs. In order to investigate the relationship between FDI and portfolio investment, I also compare a situation in which there are no restrictions on portfolio investments to one in which there are restrictions that are relaxed along with FDI restrictions. I find that country size and portfolio investment opportunities strongly affect the pattern of economic activity during transition to FDI openness, and I demonstrate that common measures of economic performance obscure the benefits of FDI openness.

3.1. Additional Assumptions

The propositions below assume that there are two countries of different sizes, where size is defined to be $N_{it}A_{it}^{1-(1-\phi)(\alpha_T+\alpha_I)}$ and thus depends on a country i 's population and level of TFP. Both countries start out closed, and then both announce an FDI openness policy σ_{it}^* in $t = 1$. In Figure 1, I display the path of the degree of FDI openness $\{\sigma_{it}\}$, which is assumed to be the same for both countries. After t^* , companies are allowed to produce at home and abroad.

I assume that $N_{it} = N_i(1 + \gamma_N)^t$ and $A_{it} = (1 + \gamma_A)^t$ for some fixed N_i and A_i and report results relative to historical trends, where γ_N is the common trend growth rate in populations and γ_A is the common trend growth rate in technologies. In other words, I divide all variables that grow (except labor inputs) by $(1 + \gamma_Y)^t$, where

$$\gamma_Y = (1 + \gamma_N)^{\frac{1-(1-\phi)(\alpha_T+\alpha_I)}{(1-\phi)(1-\alpha_T-\alpha_I)}} (1 + \gamma_A)^{\frac{1}{(1-\phi)(1-\alpha_T-\alpha_I)}} - 1.$$

For labor inputs, I divide by $(1 + \gamma_N)^t$. Lowercase letters are used to denote the detrended variables, for example, $c_{it} = C_{it}/[N_i(1 + \gamma_Y)^t]$ and $l_{it} = L_{it}/[N_i(1 + \gamma_N)^t]$. Throughout this section, the historical trend is assumed to be consistent with closed capital markets; therefore, for the equilibrium described below, $\sigma_{i0} = 0$ and $B_{i0} = 0$.⁹

In order to make precise statements about the equilibrium paths, I make three additional assumptions. One concerns the degree of FDI openness: at $t = t^* + 1$, σ_{it}^* is high enough so that the smaller country does not find it optimal to make any further expenditures in technology capital in $t > t^*$. A second assumption is that companies in the smaller country operate only domestically.¹⁰ In this case, I need only focus on FDI flows into the small country. Figure 2 shows the path of inward FDI of that country, which peaks at t^* , one period before the restrictions are actually relaxed. For the model, the FDI investment by multinationals is summarized by the second term in (2.13), which is the net new investment in tangible capital.

⁹ The equilibrium patterns do not change for $\sigma_{i0} > 0$ as long as σ_{i0} is below a particular threshold.

¹⁰ Relaxing this assumption complicates the mathematics but changes the results only slightly because the accumulated technology capital of the smaller country is lower than that of the larger country.

My final assumption, which is relevant only for the case without portfolio restrictions, is to assume that households in the larger country receive an exogenous amount of income, denoted by ϵ_t , between the periods $t = 1$ and $t = t^*$ (which could be positive or negative). The income stream is such that the interest rate is constant and equal to its historical value for all periods $t = 1, \dots, t^*$.¹¹ In practice, the income needed to ensure a constant interest rate is tiny, but this assumption lets me make precise statements about a complicated dynamic path in an economy that is so close to the economy of interest (with $\epsilon_t = 0$) that the paths cannot be easily distinguished when graphed. I refer to the related economy as the ϵ -economy.

3.2. Without Portfolio Restrictions

I begin this qualitative exercise by exploring what happens in the two countries when restrictions on portfolio investments are relaxed immediately, but restrictions on FDI are relaxed after a prespecified date t^* .

Proposition 1. The small country's output, labor, and capital stocks in the ϵ -economy are at or below their historical trends between $t = 1$ and $t = t^*$, while its consumption is above trend. The reverse is true for the large country.

Proof. Suppose that in $t = 1$, consumption c_{st} in the small country, with index $i = s$, rises relative to its historical trend, $c_{s1} > c_{s0}$. Then, between $t = 2$ and $t = t^*$, $c_{st} = c_{s1}$ since r_{bt} is constant by the choice of the $\{\epsilon_t\}$ adjustment. To be consistent with the intertemporal condition for asset holdings, this rate of interest has to equal $(1 + \gamma_y)/\beta - 1$, where γ_y is the rate of growth of per capita output, $\gamma_y = (1 + \gamma_Y)/(1 + \gamma_N) - 1$, and β is the household's discount factor.

From the intratemporal first-order condition of households (with log preferences), we know that

$$\frac{y_{st}}{l_{st}} = \frac{y_{st}^d}{l_{st}^d} \propto \frac{c_{st}}{1 - l_{st}}, \quad t = 1, \dots, t^*, \quad (3.1)$$

¹¹ If $\epsilon_t = 0$ for all t , then the equilibrium interest rate is *nearly* constant. For a plot of the interest rates with and without the income adjustment, see McGrattan (2011).

where y_{st}^d is the output of domestic companies (indexed by d) in the small country. The first equality in (3.1) follows from the assumption that countries are initially closed to all foreign investment, so all labor is supplied to domestic companies and all output is produced by them. With capital stocks initially fixed and consumption higher in period $t = 1$, we know that $l_{s1} < l_{s0}$ and $y_{s1} < y_{s0}$ if (3.1) holds. With capital fixed, we also know that labor falls by more than output in $t = 1$.

In period $t = 2$, output and labor must fall further relative to the historic trend because domestic capital stocks fall between the first and second periods. To see this, note that the capital-output ratio is pinned down by the return r_{bt} . If this return in the second period is equal to $(1 + \gamma_y)/\beta - 1$, then the capital-output ratios have to be equal to their historical levels (in $t = 0$). This fact plus the production technologies implies that labor productivity in the second period must also be at its historical level. Thus, from (3.1), we know that $y_{s2} < y_{s1}$ and $l_{s2} < l_{s1}$ since labor productivity in the second period is below labor productivity in the first.

Since the interest rate does not change between $t = 2$ and t^* , we know that $y_{st} = y_{s2}$ and $l_{st} = l_{s2}$ for $t \leq t^*$. This follows from the intratemporal condition and the fact that capital-output ratios and consumptions relative to trend are constant.

The arguments made for the small country can also be made for the large country. However, because the global resource constraint must hold, the paths relative to trend for the large country must be reversed. In other words, if consumption for the small country is above its historical trend from $t = 1$ to $t = t^*$, then consumption for the large country must be below its historical trend. This follows because output and investment are below (or above) trend by the same percentage over the period from $t = 2$ to $t = t^* - 1$ since capital-output ratios are constant. If consumption in both countries were above trend and output less investment in both countries below trend, then the global resource constraint would be violated.

Finally, we can easily show that consumption is initially above trend in the small country, which is the recipient of future FDI, and initially below trend for the large country,

which is the source of the FDI. This follows from the fact that effective TFP is higher in the small country when FDI, and hence foreign technology capital, is allowed in. For the large country there is no change in effective TFP because small country firms only produce domestically. ■

This proof of Proposition 1 is instructive in that it implies specific patterns for the key macroeconomic aggregates in the transition period between the *announcement* and the *enactment* of the policy to relax restrictions on FDI. Figure 3 shows the equilibrium paths for consumption, output, and labor in the small country (left panels) and the large country (right panels). The scale of the figures in the left panels of Figure 3 are comparable to those in the right panels, indicating that the relaxed FDI restrictions have a relatively larger impact on the small country.

Figure 3 shows that consumption in the small country rises above its historical trend at the announcement of the new policy, stays on a new higher trend until the restrictions are actually relaxed, and then rises further. At the same time, consumption in the large country is below its historical trend, but ultimately rises above trend as global production expands; after $t = t^*$, the multinationals in the large country are able to produce at home and abroad.

Equilibrium paths for output and labor relative to their historical trends are shown in the bottom half of Figure 3. I put output and labor on the same graph in order to show that in the period from $t = 2$ to $t = t^*$, they are below trend by the same percentage. When restrictions are relaxed, output in the small country rises relatively more than labor because TFP and capital are both higher. As with consumption, I find that output and labor in the large country, which by assumption has no inward FDI, is little changed.

Equilibrium paths for the capital stocks are shown in the top half of Figure 4. The domestic capital stocks fall for one period after the announcement and then remain flat until the policy is actually enacted. After $t = 1$ and before the policy goes into effect, capital-output ratios and labor productivity remain at their historical trends. When the policy is changed, investment in the technology capital of domestic companies ceases. At

this point, the optimal policy is to leave it to foreign multinationals to invest in technology capital. Total tangible and plant-specific intangible capital stocks rise because foreign companies are now investing in the small country.

With multinationals investing in intangible capital, output (shown in Figure 3) is not equal to GDP or GNP, which are typical measures of economic performance used in cross-country empirical studies. The following proposition qualifies the equilibrium paths of these series in the transition.

Proposition 2. The small country's GDP and GNP in the ϵ -economy initially, after the announcement, rise above their historical trends and then fall below trend between $t = 2$ and $t = t^*$. The reverse is true for the large country.

Proof. Recall the definitions of GDP and GNP in (2.8) and (2.12), respectively. In the first period, when the policy is announced, net factor incomes for the period are already determined; therefore, GNP must equal GDP. To show that both are above their historical trend in the small country in $t = 1$, I must show that intangible investments of domestic firms (indexed by d) in the small country (indexed by s) fall by more than output, since GDP is defined as output less the sum of investment in plant-specific intangible capital and technology capital. This is shown as follows:

$$\begin{aligned} \frac{x_{I,s1}^d - x_{I,s0}^d}{x_{I,s0}^d} &= \frac{1 + \gamma_Y}{\delta_I + \gamma_Y} \left(\frac{k_{I,s2}^d - k_{I,s0}^d}{k_{I,s0}^d} \right) \\ &= \frac{1 + \gamma_Y}{\delta_I + \gamma_Y} \left(\frac{y_{s2}^d - y_{s0}^d}{y_{s0}^d} \right) \\ &< \frac{1 + \gamma_Y}{\delta_I + \gamma_Y} \left(\frac{y_{s1}^d - y_{s0}^d}{y_{s0}^d} \right), \end{aligned}$$

where the first equality uses the capital accumulation equation after detrending all variables, the second equality follows from the fact that the capital-output ratio in the second period is equal to the historical capital-output ratio, and the inequality follows from Proposition 1. Since $\delta_I \leq 1$, plant-specific intangible investment must fall by more than output. The same argument can be made for technology capital. Therefore GDP and GNP are both above trend in $t = 1$.

In the second period, since the capital-output ratios are at their historical trends, GDP in the small country must be below its own trend by the same amount as output. In $t = t^*$, GDP falls further below its historical trend than output has fallen because investment of foreign multinationals in both tangible and plant-specific intangible capital rises above zero. GDP is lower because of the rise in plant-specific intangible investment.

The path of GNP depends on the path of portfolio investment from abroad. Since there are no portfolio restrictions, the small country borrows as soon as the policy change is announced and must make bond repayments thereafter. Thus, GNP is above GDP in $t = 2$ and below in $t = 3, \dots, t^* - 1$, with the difference between GNP and GDP equal to the interest payments $r_{bt}b_{it}$.

In the transition period, the pattern of debt can be determined from net exports which are equal to the change in debt holdings less interest payments. Net exports are equal to GDP less domestic consumption and investment—and all three of these variables are constant relative to their historical trends between $t = 2$ and $t = t^* - 1$. Thus net exports must also be constant relative to its historical trend.

The arguments made for the small country can be made for the large country, but the direction of change is reversed for the periods $t = 1$ to $t = t^*$. ■

The bottom half of Figure 4 shows the equilibrium paths for GDP and GNP. As the propositions above show, both GDP and GNP in the small country are above trend initially. But in $t = 2$, small country GDP has dropped below trend by the same amount as true output and stays constant relative to that historical trend until intangible investment by foreign multinationals rises significantly. GNP falls throughout the preliberalization period because the small country is paying portfolio income to households abroad. The large country paths are shown for comparison; as in the case of output and labor, there is a smaller impact of FDI openness in the large country.

A comparison of Figure 2 and the bottom left panel of Figure 4 clearly illustrates one of the main messages of the paper, namely, that when foreign direct investment is high, GDP is low. The reason is simple: FDI is high because foreign tangible investment is

high, GDP is low because foreign plant-specific intangible investment is high, and both investments are high when countries are open to FDI.

The rise in consumption and leisure in the small country hosting the new FDI is indicative of a positive *welfare* gain to openness, if the welfare gain is measured as the consumption increase necessary to keep the small country indifferent between remaining closed and being open. Assuming that countries have good measures of consumption, this suggests that empirical studies could use this alternative measure of economic performance instead of the ones typically used, namely, per capita GDP or GNP. I will show next that the usefulness of consumption as a proxy for economic gains depends on whether or not there are restrictions on portfolio investments. So far, I have assumed that there are no restrictions.

3.3. With Portfolio Restrictions

Now I consider what happens if restrictions on portfolio and foreign direct investments are relaxed together. In this case, $B_{i,t+1} = 0$, for both i and $t = 1, \dots, t^*$. With $\sigma_{it} = 0$ over the same period, the two economies are initially effectively closed, and the only changes in the time series are due to the anticipation of a future relaxation of the capital accounts.

Proposition 3. The small country's output and labor with full capital account restrictions are below their historical trend between $t = 1$ and $t = t^*$. The reverse is true for the large country.

Proof. If, in period $t = 1$, consumption in the small country rises relative to its historical trend, $c_{s1} > c_{s0}$, then the intratemporal first-order condition of households in (3.1) implies that labor and output fall initially. With capital fixed, labor falls more than output.

With no borrowing or lending allowed across countries, total investment in period $t = 1$, $y_{s1} - c_{s1}$, must be below trend. With returns equated across assets, investment in all three types of assets—tangible capital, plant-specific intangible capital, and technology capital—must also be below trend.

In period $t = 2$, output and labor must fall further because domestic capital stocks are lower between the first and second periods when investment in $t = 1$ is below trend. Households cannot borrow from abroad; thus, output, investment, and labor continue to fall until $t = t^*$, and net exports remain equal to zero until the restrictions on FDI are relaxed.

Again, the same arguments can be made for the large country, but because the global resource constraint must hold, the paths relative to trend for the large country must be reversed. Because the small country is the recipient of future FDI while the large country is its source, the initial consumption in the small country must be above its historical trend, and the initial consumption in the large country must be below. Otherwise, the global resource constraint would be violated. ■

3.4. A Comparison

The two situations, with and without portfolio restrictions, are compared in Figure 5. Clearly, the ability to borrow from abroad affects an economy's transition to FDI openness. Without this ability, the adjustments are slow before $t = t^*$, but rapid when restrictions on capital accounts are relaxed.

If portfolio investments are restricted, the economic benefits of the new policy are not easily detectable—either in terms of improved consumption and welfare or in terms of improved production and employment—until after a threshold degree of openness has been reached.

The results in Figures 3–5 shed light on what Gourinchas and Jeanne (2007) have called the “allocation puzzle.” According to standard neoclassical theory, countries with faster productivity growth should attract more foreign capital, but observed capital flows are not consistent with this prediction. They find that countries with lower GDP and TFP growth receive most of the capital inflows. In the simple two-country version of the model with countries differing in size, I find this too. To be specific, let me define *measured* TFP

as

$$\text{TFP}_{it} = \frac{\text{GDP}_{it}}{K_{T,it}^{1/3} L_{it}^{2/3}},$$

where $K_{T,it}$ is the total tangible capital in country i . As in the case of GDP, measured TFP is abnormally low when inward FDI is abnormally high. This is true even if true TFP does not change. Thus, care must be taken when diagnosing economies with low or slow-growing GDP and TFP.

In McGrattan (2011), I show how the results change as I vary the length of the transition to openness—the time delay between policy announcement and policy enactment—the relative sizes of countries, the maximal degree of openness, and the share of income that goes to technology capital. The qualitative features shown in Figure 3–5 are not altered.

4. A Quantitative Assessment

Next, I consider more realistic choices for the time paths governing the relative size and degrees of openness in the world economy and the number of countries. I enlarge the model to a 104-country version parameterized with data from the World Bank’s *World Development Indicators* (WDI), for the period 1980–2005.¹² After demonstrating that the model generates empirically consistent employment shares of affiliates at home and abroad, I simulate transition paths and get a result like those of many other studies: no systematic pattern between the degree of FDI openness and the level of economic growth predicted by the model.¹³ But then I go beyond other studies. For each country in the sample, I also estimate the growth impact and welfare gains for the country of unilaterally relaxing capital market restrictions. I find that the boost to annual per capita GDP growth over the period 1980–2005 is large, as much as 7 percentage points. I find that the welfare gains

¹² For data sources, see Appendix A. See Appendix B and McGrattan (2011) for details on the computational methods. Note that in the 104-country version of the model, I allow for small quadratic costs of adjusting capital stocks. This approach avoids numerical difficulties due to binding nonnegativity constraints on investments.

¹³ Many factors are left out of the analysis here in order to highlight the impact of relaxing capital market restrictions on economic performance. Sensitivity analysis in McGrattan (2011) shows that the main results are not overturned if changes in other factors are included.

are also large, as much as 460 percent in consumption-equivalent units. Both effects are inversely related to country size.

4.1. Model Specifications

Inputs in the larger version of the model are chosen so that it generates *trends* in inward FDI to GDP that mimic the trends in the data. Because the focus is on trends, a period is defined as five years. The choice of 104 countries is dictated by data availability on inward FDI, net portfolio investment, GDP, and population. I assume that countries have four differences: (1) relative technology levels A_i , which I assume are on trend and chosen so that real GDP per capita in 1980 is the same in the model and the data; (2) populations N_{it} , which are taken directly from the WDI data; (3) degrees of FDI openness σ_{it} , which are chosen so that the ratio of inward FDI to GDP in the model has the same trend as a moving average of the actual series; and (4) the number of periods that international borrowing B_{it} is held at zero, which I denote as T_c and set by comparing net portfolio investments in the model and the data.¹⁴

The implied productivities, A_i , and the path for populations, N_{it} , at five-year intervals are reported in Table 1 for all countries i in the sample (along with the country codes used in the following figures). All estimates are relative to the United States, which is normalized to be 100. After 2005, I assume that the populations relative to that of the United States stay at their 2005 level. As the values in the table indicate, the dispersion in country relative size is large, which is not surprising given the wide range of TFPs and populations.

The path of the degree of openness, σ_{it} , is reported in Table 2 for all countries i along with the number of periods during which international borrowing is held at zero. For many of the countries, using a step function for the sequence σ_{it} generates a realistic pattern for the ratio of FDI to GDP. Thus, the time path used in the two-country example is not atypical.

¹⁴ As before, measured TFPs are time-varying since they depend on time paths of population and technology capital.

For all other parameters, I use estimates from my 2010 study with Prescott of the U.S. current account, which are listed in Table 3.¹⁵ To ensure that none of the results rest critically on any of these choices, I have also done an extensive sensitivity analysis. (See McGrattan, 2011.)

In Appendix B and McGrattan (2011), I provide details on the first-order conditions of the maximization problems and the methods used for computing equilibria in this model with many states. The main innovation here is the use of parallel processors, one for each country.

4.2. A Test

Before turning to the main quantitative result, I first test the model by checking to see if it generates realistic employment shares between domestic and foreign firms. I do this because I have abstracted from many factors that differentiate countries, most importantly for the purposes here, their geography, language, and trade policies, which potentially affect these shares. I find that despite those abstractions, the model's employment predictions are quite good.

In Figures 6–8, I show evidence from three sources: the Organisation for Economic Co-operation and Development (OECD) statistics on inward activity of multinationals and employment (OECD, 2010a, 2010b, 2010c), the survey of foreign affiliates in the United States from the Bureau of Economic Analysis (BEA) (U.S. Department of Commerce, 2007), and the BEA's survey of U.S. affiliates abroad (U.S. Department of Commerce, 2008). I use data on manufacturing employment, since that measure is available and most relevant; service industries have been a much smaller share of multinational operations to date.

Figure 6 compares for each country the predicted and actual employment under foreign control as a share of the country's total employment. Data are available for 17 OECD

¹⁵ Averages are used for time-varying tax rates.

countries. The graph shows that the model does well on this dimension: the correlation between the predicted and actual shares is 0.82.

Figure 7 compares the predicted and actual employment of foreign affiliates in the United States by country of origin. The countries in the figure cover 88 percent of all foreign employment in U.S. manufacturing. In the model, these same countries cover 86 percent of all foreign employment in the United States. The correlation between the predicted and actual share is 0.80.

Figure 8 compares the predicted and actual employment of U.S. affiliates abroad relative to employment in the host country. One country—Canada—is not shown because the actual employment in Canada is much higher than the model predicts. Here, geography does matter; in the model, Canada is no different from any other developed country with 30 million people, but in reality, it has close ties with the United States that are unique: it is geographically close, shares a language, and is a partner in a trade union. Including Canada, the correlation between the predicted and actual employment shares for U.S. affiliates is 0.39; excluding Canada, the correlation is much higher, at 0.73.

Overall, the predicted and actual employment shares match up well.

4.3. Current Predictions

Since the parameterized model passes the employment share test, we can expect its other predictions to be at least reasonable. For the issue here—the relationship between FDI openness and growth—the model predicts what many empirical studies have found: no positive relationship.

Figure 9 is the analogue of Lucas’s (2009) Figure 2, which compares countries doing a little and a lot of trade. Here, I distinguish instead between countries doing a little or a lot of inward FDI. The x -axis of Figure 9 shows the initial real GDP per capita relative to the level of the country parameterized to match U.S. observations. The y -axis is the annual growth rate in real GDP per capita over the period 1980–2005. This rate is relative to the growth rate of the country parameterized to match U.S. observations. Thus, an annual

growth rate of zero implies that a country is growing at the same rate as the country matched to the United States. Rates above zero imply that the country is catching up to the U.S. level of per capita GDP, and rates below zero imply that it is falling behind. I use a cut-off for the average FDI to GDP of 1.8 percent and identify only countries that are above it, which is half of the sample. Other cut-offs for FDI could be used, and I could replace growth in GDP by growth in TFP, but the message would be the same: the data show no obvious relationship between capital restrictions and economic performance.

Another way to demonstrate this result is by way of a cross-country regression of growth on initial per capita GDP and the ratio of FDI to GDP.¹⁶ In Table 4, I report the results of such a regression for both the data and the model. The coefficient of interest is a_2 . This coefficient is 0.052 in the data, but is not significantly different from zero. In the model, the estimate is 0.046 with a smaller standard error than in the data, but it is not economically significant. If I double the FDI to GDP ratio from 2 percent (which is close to the median in my sample) to 4 percent, the predicted change in the growth rate for real GDP per capita relative to the U.S. growth rate remains less than 0.1 percentage point.

4.4. Potential Gains

Still, the lack of a robust positive relationship between relationship between FDI openness and growth does not necessarily mean that the effects of FDI openness are not positive and large. To demonstrate that, I compute the economic impact of relaxing capital market restrictions almost completely for one country at a time. I estimate the benefits in terms of higher GDP growth and welfare and find that they can be huge, especially for small countries.

To be more specific, I run the following counterfactual experiment: for each country i , I increase the $\{\sigma_{it}\}$ to 0.95 for all periods after 1980, and I remove all restrictions on portfolio investments.¹⁷ In each case, I calculate the growth in per capita GDP less the

¹⁶ Many of the studies surveyed by Kose, Prasad, Rogoff, and Wei (2009) include other control variables about which the model is silent. But researchers have found that adding them reduces the already small coefficients on the ratio of FDI to GDP.

¹⁷ I cannot raise σ_{it} to 1 for two reasons. First, at 1, there is an indeterminacy in terms of who should

growth rate computed in the benchmark model and the consumption-equivalent gain, that is, the increase in consumption needed to keep the country indifferent between the old and new policy.

Figure 10 shows the prediction for GDP growth when countries are close to completely open relative to that of the benchmark parameterization.¹⁸ The differences in predicted growth rates are plotted relative to country size (in log scale). As expected from the earlier propositions, there is an inverse relationship between a host country's growth following capital market liberalization and its relative size. In almost all cases, the boost in growth in transition is substantial, with the highest annual estimates around 7 percentage points.¹⁹

Figure 11 shows the predicted welfare gains for each country unilaterally opening their capital markets. As with growth, there is an inverse relationship between gains and the country's relative size, which is close to linear in logarithms. The smallest potential gain is found for the United States, at a 4 percent increase in consumption, and the largest gain for the Solomon Islands, at a 460 percent increase. If we compare two countries close to the best-fit line in Figure 11—say, Great Britain and Botswana—we find that a country smaller by a factor of 300 has a welfare gain that is 11 to 12 times larger. In other words, for small countries, the potential gains to openness are huge.²⁰

5. Conclusion

Here, I have studied the equilibrium paths of a multicountry dynamic general equilibrium model as countries relax restrictions on portfolio and foreign direct investment. By taking account of a transition period, the model reconciles theoretical claims that allowing FDI leads to higher growth and welfare for host countries with the lack of robust empirical

produce technology capital. Second, it is difficult numerically to raise σ_{it} much higher than 0.95 with many countries near corners in terms of investment.

¹⁸ Results for Figures 10 and 11 are also reported in tables in McGrattan (2011).

¹⁹ As in basic neoclassical growth model, increased growth rates in my model are temporary as countries catch up. See Henry (2007).

²⁰ The inverse relation between gains and size is also found in work by Ramondo and Rodríguez-Clare (2010b), who estimate the gains of moving from autarky to current-day capital and current account restrictions for 19 OECD countries.

evidence for such benefits. In the model, benefits to FDI openness are large, but only eventually, once some threshold of openness is reached.

This result implies at least two research challenges. More work is required to delineate the characteristics of the openness threshold. And the standard method of analyzing the effects of FDI openness must be abandoned. After all, even using the method here, on the data generated by my model, results in the mistaken conclusion that relaxing restrictions on capital movements is not beneficial to the host country.

Appendix A. Data Sources

The World Bank's *World Development Indicators* is the source of individual-country data used in this study. All countries with complete time series for the period 1980–2005 are included.²¹ (The complete list of countries is shown in Tables 1 and 2.) Specifically, I construct the ratio of inward FDI relative to GDP and real GDP per capita using the following variables (with WDI codes in parentheses):

- Foreign direct investment, net inflows, in current U.S. dollars (BX.KLT.DINV.CD.WD);
- Portfolio investment in current U.S. dollars (BN.KLT.PTXL.CD);
- GDP in current U.S. dollars (NY.GDP.MKTP.CD);
- GDP in constant 2000 U.S. dollars (NY.GDP.MKTP.KD);
- Total population (SP.POP.TOTL).

The OECD and the BEA are the sources of data used to construct employment shares of foreign affiliates shown in Figures 6–8. Specifically, I use the following:

- Figure 6: OECD.Stat Inward activity of multinationals (and, as a supplementary source, the OECD Factbook 2010);
- Figure 7: FDIUS Establishment Data for 2002, Table A1.9, has employment of foreign-owned establishments in the United States by country;
- Figure 8: USDIA 2004 Final Benchmark Data, Table I.H3, has employment of affiliates, and the OECD STAN database for Structural Analysis has total manufacturing employment in the host country.

²¹ See McGrattan (2011) for results based on a subsample of the 104 countries, namely, those with complete inward FDI data (variable 4555) for the period 1980–2005 in the International Monetary Fund's *Balance of Payments* (IMF, 1980–2010).

Appendix B. Computational Methods

In this appendix, I briefly describe the two main numerical issues that arise in computing equilibria for the 104-country version of the model: the large dimensionality of the state space and the nonnegativity constraint on investment decisions.²²

The issue of dimensionality arises because the investment decisions of firms in one country affect decisions in all other countries. To handle this, I used a parallel computer and a code that uses the message passing interface (MPI). An initial guess is made for the vector of interest rates, wages in all countries, and transfers in all countries. If there are I countries and T time periods, a fixed point must be found for $(2I + 1)T - 1$ prices and transfers. The guess is distributed by the master processor to all slave processors. Given prices and transfers, equilibrium quantities are computed on the slave processors, passed back to the master, and the guess for the prices and transfers is updated. A fixed point in quantities must also be solved at each iteration. This is done with a standard Newton method, although I have found that analytical derivatives of the Jacobians are necessary to avoid very slow computations given the large number of unknowns being computed. A fixed point must be found for $(2I + 4)T$ quantities that include consumptions, labor supplies, bond holdings, investments in technology capital, I investments in tangible capital, and I investments in plant-specific intangible capital for each period. In all, $(4I + 5)T - 1$ prices and quantities are computed.

The other issue is, again, the nonnegativity of investment decisions. As small countries relax capital restrictions and let technology capital flow in from abroad, the returns to investing in their own technology capital fall—possibly nonmonotonically, but ultimately to zero. With a large number of countries in the model, it is difficult to apply standard penalty function methods to avoid negative investments. Instead, I allow for (small) quadratic adjustment costs in the accumulation equations (2.4)–(2.6) to aid the solution of the fixed points in prices and quantities. For countries that are close to the corner at the start of the simulation (which is matched up to 1980 observations), I assume that they are at the corner and set the appropriate investments to zero.

²² For full details of the methods used and equations solved, see McGrattan (2011).

TABLE 3. MODEL CONSTANTS AT ANNUAL RATES^a

| PARAMETER | EXPRESSION | VALUE |
|-----------------------------------|---------------------------------------|-------|
| PREFERENCES | | |
| Discount factor | β | .98 |
| Leisure weight | ψ | 1.32 |
| GROWTH RATES (%) | | |
| Population | γ_N | 1.0 |
| Technology | γ_A | 1.2 |
| INCOME SHARES (%) | | |
| Technology capital | ϕ | 7.0 |
| Tangible capital | $(1 - \phi)\alpha_T$ | 21.4 |
| Plant-specific intangible capital | $(1 - \phi)\alpha_I$ | 6.5 |
| Labor | $(1 - \phi)(1 - \alpha_T - \alpha_I)$ | 65.1 |
| DEPRECIATION RATES (%) | | |
| Technology capital | δ_M | 8.0 |
| Tangible capital | δ_T | 6.0 |
| Plant-specific intangible capital | δ_I | 0 |
| TAX RATES (%) | | |
| Labor wedge | τ_l | 34 |
| Profits | τ_{pi} | 37 |
| Dividends | τ_d | 28 |

^aSee McGrattan and Prescott (2010) for details on these parameter choices.

TABLE 4. IMPACT OF FDI ON PER CAPITA GDP GROWTH^a

Regression: $g = a_0 + a_1gdp_0 + a_2fdi/gdp$

g = annual growth in real GDP per capita relative to US, 1980–2005 (US = 0)

gdp_0 = real GDP per capita relative to US in 1980 (US = 1)

fdi/gdp = average ratio of FDI to GDP (in percentages), 1980–2005

| | Coefficient | | |
|-------|------------------|-----------------|-----------------|
| | a_0 | a_1 | a_2 |
| Data | −1.062 (.288) | 1.065 (.660) | 0.052 (.063) |
| Model | −0.209 (.123) | 0.174 (.264) | 0.046 (.026) |

^aNumbers in parentheses are standard errors.
