Urban Policy Effects on Carbon Mitigation

Matthew E. Kahn

16.1 Introduction

Suppose that a household was choosing between living in Houston or San Francisco. In each city, what would this household's annual carbon footprint be? Glaeser and Kahn (2010) estimate that a standardized household would create 12.5 extra tons of carbon dioxide per year if it moved to Houston rather than moving to San Francisco. In Houston, the same household drives more, lives in a bigger home, uses more residential electricity—electricity that is generated by power plants with a higher carbon emissions factor. Using data from the year 2000 across sixty-four major metropolitan areas, Glaeser and Kahn (2010) document that Pittsburgh is the city with the median residential household footprint of 28.3 tons of carbon dioxide per year, while San Francisco is the third “greenest” metropolitan area, and Houston is the third “brownest” metro area. This cross-sectional descriptive work creates a benchmark for comparing cities' household carbon emissions from transportation, electricity consumption, and home heating, at a point in time and tracking city trends over time.

Given that greenhouse gas emissions are a global externality, households are unlikely to internalize the carbon consequences of moving to a city such as Houston rather than San Francisco. Why is San Francisco “greener” than Houston? San Francisco is blessed with a temperate climate. Northern California's electric utilities emit less greenhouse gas emissions than their Texas

Matthew E. Kahn is professor in the Institute of the Environment, the Department of Economics, and the Department of Public Policy at the University of California, Los Angeles, and a research associate of the National Bureau of Economic Research.

I thank Varun Mehra, Frank Wolak, and Catherine Wolfram for useful comments. For acknowledgments, sources of research support, and disclosure of the author's material financial relationships, if any, please see <http://www.nber.org/chapters/c12128.ack>.

counterparts. Due to its amenities, land prices are higher in San Francisco, and its residents live in smaller homes than their Houston counterparts. Land prices are highest downtown, and this encourages economy activity to be highly compact. Such population density in San Francisco encourages households to live a walking, “new urbanist” life. This low-carbon lifestyle would be rare in sprawling Houston.

Over the last 100 years, people and jobs have been moving away from center cities. The average person who lived in a metropolitan area lived 9.8 miles from the city center in 1970, and this distance grew to 13.2 miles by the year 2000. While privately beneficial, this trend has helped to exacerbate the challenge of mitigating greenhouse gas production. Suburbanites drive more and live in larger homes that require more heating and cooling than their urban counterparts.

This chapter uses three different data sets to document that households who live in center cities drive less, use public transit more, and consume less electricity than observationally similar households who live in the suburbs. This center city/suburban differential is largest in the Northeast’s monocentric cities such as New York City. Given that households choose where to live, this differential could be caused by both residential self-selection and a true causal “treatment effect” of urban living. If these correlations are due to a treatment effect, then any pro-center city policy, such as policies directed toward reducing inner-city crime, is likely to reduce a metropolitan area’s carbon footprint.

16.2 Urban Transportation

16.2.1 Miles Driven as a Function of Urban Form

The Department of Transportation has recently released the 2009 National Household Transportation Survey (NHTS) micro data.¹ This micro data set is distinctive because it reports household vehicle mileage for a large representative sample of households. Using a special version of the data set that has census tract identifiers, I restrict the sample to households living within thirty-five miles of a major city center. For each household, I observe which metropolitan area it lives in, its distance to the city center, and its distance to the closest rail transit station using data from Baum-Snow and Kahn (2005). I estimate ordinary least squares (OLS) regressions for household i living in census tract l in metropolitan area j using observations on over 92,000 households based on equation (1):

$$(1) \quad \text{Miles}_{ij} = \text{MSA}_j + B_1 \cdot \text{Demographics}_i + B_2 \cdot \text{Urban Form}_{ij} + U_{ij}$$

In this regression, the dependent variable is the household’s total miles driven in the last year. I trim the dependent variable and set the dependent

1. See <http://nhts.ornl.gov/download.shtml#2009>.

variable equal to the 99th percentile of the empirical distribution for observations in the top percentile. In table 16.1 columns (1) and (2) are identical except that the results in column (2) include metropolitan area fixed effects. In these regressions, I control for household income, the number of people in the household, and the age of the head of the household. Controlling for these demographic factors, my primary interest is to measure the association between a household's total miles driving and its location within the metropolitan area, the population density where it lives, and where it lives within one mile of a rail transit line. The results are roughly similar with and without metropolitan area fixed effects. As shown in table 16.1 distance from the city center is positively correlated with miles driving. Moving a household from the 25th percentile of the distance to the city center distribution to the 75th percentile of this distribution is associated with driving an extra 1,300 miles per year. A household's census tract's population density is negatively correlated with miles driving. Moving a household from the 25th percentile of the population density distribution to the 75th percentile of this distribution is associated with a driving 2,400 fewer miles per year. In both regressions, proximity to a rail transit line has a negative effect on

Table 16.1 Household miles driven as a function of urban form

	(1)	(2)
Log(Distance to city center)	1239.66 [217.000]***	1140.41 [254.272]***

Age of head of household	-77.72 [12.073]***	-77.71 [11.589]***
Constant	6822.21 [2752.336]**	4751.63 [3365.890]
Observations	92,597	92,597
R ²	0.26	0.27
Geographical fixed effect	No	Metro
Household income fixed effect	Yes	Yes

Notes: The unit of analysis is the household. The dependent variable is the household's annual mileage. The sample includes all households in the 2009 National Household Transportation Survey (NHTS) who live in a census tract whose centroid is within thirty-five miles of a city center. Standard errors are reported in brackets. The standard errors are clustered by census tract. The omitted category is a household who lives more than a mile from the closest rail transit line. Dummy variables for the household's income category are included in the regressions, but their coefficients are suppressed. Miles driven has a mean of 17,925 and a standard deviation of 19,061.

***Significant at the 1 percent level.

**Significant at the 5 percent level.

driving. All else equal, households who live within one mile of a rail transit line drive 1,900 fewer miles per year than households who live more than one mile from a rail transit line. This correlation must reflect both sorting effects (selection) and a treatment effect due to easy access to fast public transit.

These correlations are suggestive about the role that urban policy plays in encouraging driving less. If households were randomly assigned to homes, then OLS estimates of equation (1) would be of immediate use to policy-makers in determining how urban policies affect an important part of the household carbon footprint (miles driven). But we know that households self-select where they want to live. Liberal environmentalists are likely to self-select and choose to live in the high density areas, close to center city, and close to subway stations (Kahn and Morris 2009). An active research agenda in urban planning examines the importance of attitudes, beliefs, and preferences in determining residential location choice and travel behavior (e.g., Cao, Handy, and Mokhtarian 2006; Cao, Mokhtarian, and Handy 2007; Krizek 2003).

16.2.2 Public Transit Use from 1970 to 2000

In previous research, I have examined how worker public transit varies across cities and over time for cities that have expanded their rail transit systems (Baum-Snow and Kahn 2005). This work has public policy implications because rail transit construction is a favorite urban policy for encouraging center city growth and compact urban development.

Communities differ with respect to their distance to the central business district (CBD) and their distance to rail transit stations. Rail transit is a fast means for commuting to the city center. As discussed in Glaeser and Kahn (2001, 2004), a fundamental challenge for urban policy in battling climate change is that jobs continue to suburbanize. When people work in the suburbs, they do not use public transit to commute there. But, in cities such as New York City with a vibrant center city core, public transit remains an important commuting mode.

To examine how rail transit access affects commute mode choice, I use census tract level data for forty-two major metropolitan areas. I examine how proximity to the CBD and proximity to rail transit correlates with public transit use. I use a geocoded census tract panel data set from 1970, 1980, 1990, and 2000 and observe public transit use by workers (the percent of the census tract who commute using public transit), while restricting the sample to tracts within thirty-five miles of a major city's CBD.

In table 16.2, the dependent variable is a tract's public transit use share. Each column reports a separate regression. I include all metropolitan areas that are within thirty-five miles of a city center that has a rail transit system. Controlling for metropolitan area fixed effects, several facts emerge. Relative to the omitted category (1970), the propensity to commute by public transit has declined each decade. The propensity to commute by public transit

Notes: This table reports three ordinary least squares regressions. The omitted category is a 1970 census tract whose centroid is more than one mile from the closest rail transit station. In columns (1) to (3), the sample includes all census tracts whose centroid is within thirty-five miles of a central business district (CBD) in a city with a rail transit system. Standard errors are reported in brackets. The dependent variable has a mean of .16 and a standard deviation of .19.

***Significant at the 1 percent level.

declines with distance from the city center and increases if a tract's centroid is within one mile of a rail transit station. These results are robust to controlling for tract demographics such as the share black and the share college graduate (see column [2]).

16.3 Differences in Residential Energy Consumption between Urban and Suburban Households

In this section, I examine household residential energy consumption for center city versus suburban residents, and I compare how energy consumption varies across geographical regions of the nation. I use micro data from the 2005 Residential Energy Consumption Survey (RECS) for households who live in urban and suburban areas.² While the RECS data does not pro-

2. See <http://www.eia.doe.gov/emeu/recs/recspubuse05/pubuse05.html>.

vide information on the exact metropolitan area where a household lives, it does provide information on the household's census division, cooling degree days where the home is located, and the household's urban versus suburban status. I estimate versions of equation (2) for household i living in census division j .

$$(2) \quad Y_{ij} = \text{Division}_j + B_1 \cdot \text{Demographics}_i + B_2 \cdot \text{Suburb}_{ij} + U_{ij}$$

Controlling for a household's income and the number of people in the home, why would electricity consumption differ for suburban versus urban households? In a classic monocentric city, all jobs are located in the CBD. Land prices decline with distance from the city center to compensate households for longer commutes. If land prices are lower in the suburbs, then suburban homes will be larger, and the households who live there will consume more energy. As documented by Glaeser and Kahn (2001, 2004), employment has been suburbanizing but major center cities such as New York City and others in the Northeast continue to be major employment centers. I predict that suburbanites in regions where a large share of employment continues to be downtown (and, thus, the monocentric model has more predictive power) will feature a larger center city/suburb energy consumption differential.

The energy consumption regressions are reported in table 16.3. In column (1), the dependent variable is the log of household electricity consumption. Controlling for the household's income and demographics, the average suburbanite outside of the Northeast region consumes 10 percent more electricity than the average urbanite. In the Northeast region, this differential is much larger. The average suburbanite in the Northeast consumes 51 percent more electricity than the average urbanite. The divisional dummies show the spatial variation in energy consumption with the East South Central division having the highest residential electricity consumption.³ Column (2) shows a similar Northeast urban/suburban differential for natural gas consumption. This suburban/center city differential could simply reflect selection rather than a treatment effect. In column (3), the dependent variable is a dummy that equals one if the household lives in a single detached home. Single detached homes are likely to be larger than apartments in multifamily housing. Larger homes require more electricity. The probability that a household lives in single family home is higher in the suburbs and much higher (23.5 percentage points) in the Northeast suburbs. This evidence supports the claim that the urban/suburban electricity consumption gap is larger in monocentric cities because of the within metropolitan area differences in the housing stock. In a metropolitan area with a uniform distribution of employment and no spatially differentiated amenities, I would

3. These states include Alabama, Kentucky, Mississippi, and Tennessee.

not expect to observe spatial differences in residential energy consumption because the price of land would be the same throughout the area.

16.4 Conclusion

The macro debate about the costs and benefits of adopting carbon pricing has not discussed how carbon mitigation incentives will affect competition

between center cities and their suburbs or between low-carbon cities such as San Francisco and high-carbon cities such as Houston. The low-carbon city is a city that is compact and dense and offers fast, frequent public transit that helps people commute to downtown.

Across regions, there are large differences in the household carbon footprint. Glaeser and Kahn (2010) find that cities in California, such as Los Angeles, San Diego, and San Francisco, have the smallest residential carbon footprint, while cities in the South, such as Memphis, Oklahoma City, Houston, and Nashville, have the largest carbon footprint. Their results suggest that housing development policies that lower barriers to development in California's coastal cities would "green" the overall national average. Housing economists have ranked cities with respect to the stringency of their antigrowth policies. The low-carbon cities identified by Glaeser and Kahn tend to be the same cities that have high land use regulation (Glaeser, Gyourko, and Saks 2005; Quigley and Raphael 2005). Glaeser and Kahn (2010) argue that housing regulation does not cause a low carbon footprint. They argue that the antigrowth cities are green because of their local climate conditions and their relatively low electric utility emissions factor (using natural gas rather than coal). This claim merits future research.

If carbon legislation is passed soon, the residents of the low-carbon cities will face less of a tax burden, and this will be capitalized into local land prices. Previous incidence studies have focused on geography and income categories but not the center city/suburbs dimension (Hassett, Mathur, and Metcalf 2007). The introduction of a significant carbon tax may help to reverse a fifty-year trend in the suburbanization of households and firms (Glaeser and Kahn 2004).

Such a tax could reduce the current carbon gap between cities such as San Francisco and Houston. In the long run, in the presence of such a tax, Houston's transport infrastructure, residential building stock, and portfolio of electric utilities might resemble San Francisco's. Urban economists have tried to use the "natural experiment" of the Organization of Petroleum Exporting Countries (OPEC) oil shocks to examine whether high gas prices encourage densification (Muth 1984). These short-run shocks did not increase the demand for center city living in the 1970s.

This chapter's evidence suggests that center city residents do produce less carbon emissions than their suburban counterparts. A productive future line of research could use panel data to disentangle whether the observed correlation between center city living and the low-carbon lifestyle represents a self-selection effect or a true causal effect.⁴ If future research substantiates the causal role of center city living, then this raises the public policy issue of how

4. See Eid et al. (2008) for a recent study that uses panel data to attempt to estimate the impact of urban form on obesity. By observing weight changes for migrants from center cities to suburbs (and vice-versa), they reject the claim that "sprawl is making us fat."

do we encourage more households to live downtown? Policies that improve the center city's quality of life and local public goods bundle can achieve this goal. The vibrancy of a downtown can be spurred by fighting crime and by improving urban public schools (Berry Cullen and Levitt 1999).
