NBER Working Paper No. 16547
November 2010
JEL No. C9,C91

ABSTRACT

A stylized fact is that agents respond more acutely to negative than positive stimuli. Such findings have generated insights on mechanism-design, have been featured prominently in policymaking, and more generally have led to discussions of whether preferences are defined over consumption levels or changes in consumption. This study reconsiders this stylized fact. In doing so, it provides insights into an important domain wherein positive stimuli induce a greater response than negative stimuli: a principal-agent game with reputational considerations and with the agent on the market's short end. This common setting represents an important feature of labor markets with involuntary unemployment.

1. Introduction

The principle of retaliation is as old as mankind. As far back as the Hammarabian code some 3000 years ago, retaliation of some form has served to organize behavior in both market and non-market situations. Perhaps illustrating the importance of revenge most succinctly is the Biblical injunction of Exodus 21:23-25: “Life for life, eye for eye, tooth for tooth... bruise for bruise.” For their part, scholars have explored the importance of negative actions alongside their seemingly more benign cousins, positive actions.

One of the key insights that can be taken from the decades of research within the social sciences is that reciprocity in general is important, and that negative actions toward an individual induce a greater behavioral response than comparable positive actions.² This stylized fact is perhaps best illustrated in the words of Baumeister et al. (2001), who provide a broad survey of several areas of study examining positive and negative reciprocity, and conclude that (p. 354-55, italics added): “The breadth and convergence of evidence, however, across different areas were striking, which forms the most important evidence. In no area were we able to find a consistent reversal, such that one could draw a firm conclusion that good is stronger than bad. *This failure to find any substantial contrary patterns occurred despite our own wishes and efforts...Hence, we must conclude that bad is stronger than good at a pervasive, general level.*”

Within economics, such results have served as the classic example of loss aversion – that people are more sensitive to negative realizations than to positive realizations of uncertainty (Tversky and Kahneman (1991)) – have played an important role in policymaking (see List (2003)), and have informed mechanism design. In terms of the latter, the principal is confronted with an interesting decision problem if framing of the incentive scheme matters to agent behavior or the number of instruments available to the principal is constrained. In this manner, choosing between carrots and sticks, for example, plays an important role in the outcome (see Andreoni et al. (2003)). More generally, scholars have frequently remarked that this feature of human preferences represents one of the most robust general behavioral patterns in the social sciences (see the citations in Baumeister et al. (2001)).

In this study, we explore a general setting wherein economic theory provides predictions that positive reciprocity should be stronger than negative reciprocity. The two key features are that the agent is on the short end of a market that includes reputational considerations and that being out of the market provides less utility than being a participant. Under this design, a worker that respects her initial affective reaction and punishes the employer will find herself unemployed. Alternatively, a worker who

² A particularly simple exposition involves no more than asking subjects to list emotions within a time limit (Van Goozen and Frijda (1993)). The number of negative emotions listed almost always exceeds positive ones. Along similar lines, Oehman et al. (2001) found that people identified threatening faces more quickly and accurately than happy faces. Such negative visual stimuli also induce larger amplitude brain responses than positive ones (Ito et al. (1998)). Generally, the negative domain commands affect and cognition more than the positive. In their survey, Baumeister et al. (2001) somewhat playfully draw our attention to Fiedler’s (1982) finding that nobody has ever written a successful novel about a happy marriage; there is something about negative events that seizes our attention. Similar to scholars in other social sciences, economists have found that negative events also call forth greater responses than their positive counterparts (see, e.g., Offerman (2002), Pereira et al. (2006) and Al-Ubaydli and Lee (2009)).

is nice to the employer will be more likely to be employed in the next period. Since being employed dominates unemployment, we predict that the worker will restrain herself and will not follow the initial affective reaction. On the other hand, if the employer is nice, the worker will reciprocate strongly since in this situation not only is she employed, but also by a nice employer. In other words, we predict that in our setup positive reciprocity will be stronger than negative reciprocity.

To test our theory, we design a simple controlled laboratory experiment, which yields several insights. First, consonant with the literature, agents reciprocate. And, when the interactions are anonymous, negative reciprocity is slightly more important than positive reciprocity, but not significantly so. Also consonant with the literature is the fact that agents become emotionally charged when treated poorly. Yet, this emotional charge does not readily transfer to actions when realistic institutional features are in place. For example, when agents can form reputations, they respond much more acutely to positive than to negative stimuli, serving to reverse the previously documented findings on the relative strengths of negative and positive reciprocity. Second, the data suggest that the source of the behavioral differences observed is strategic, rather than a change in the social norm of reciprocation in a gift exchange setting. Finally, the results also raise a methodological contribution of some import. Although the literature has implicitly drawn a parallel between the strength of reciprocal behaviors and other phenomena such as the Heisenberg Uncertainty Principle, our analysis highlights a critical distinction: unlike in quantum mechanics, people responding more acutely to negative than positive stimuli is not a guaranteed behavioral phenomenon. Rather, its presence and magnitude depend heavily on institutional features that can only be understood with appropriate theoretical and empirical modeling.

The remainder of our study proceeds as follows. Section 2 contains the experimental design. Section 3 summarizes the experimental results. Section 4 concludes.

2. Experimental design

To provide insights into measuring the strength of positive and negative reciprocity, we designed a simple two treatment experiment to test three conjectures. First, in one-shot environments, negative reciprocity is stronger than positive reciprocity. Second, in a repeated environment with a threat of exclusion, positive reciprocity is stronger than negative reciprocity. Finally, any observed difference in behavior across the two environments is not driven by affective reactions. In other words, when we condition on affective reactions, behavioral differences should remain.

The game played by subjects is a discrete version of the trust game (Berg et al. (1995)) where the agent (worker) has the opportunity to punish as well as reward. It is also repeated with an opportunity for principals (managers) to choose among the workers in each period. We begin by describing the simple stage game.

1. Stage game

There are two players: a manager and a worker who play the stage game in Figure 1. In each column vector of Figure 1, the top (bottom) number is the manager's (worker's) payoff. The manager has three actions: *kind*, *neutral* and *unkind*. After the manager makes her choice, the worker observes the manager's choice and has three available actions: *reward*, *neutral* and *punish*.³ Similar to Offerman (2002), the payoff consequences of actions are separable across the choices of each player. If the manager plays *neutral*, then both players' payoffs are unchanged. If the manager plays *kind*, then she loses 10 points and the worker gains 15 points. If the manager plays *unkind*, then she gains 15 points and the worker loses 15 points. Note that *kind* and *unkind* have symmetric effects on the worker's payoff.

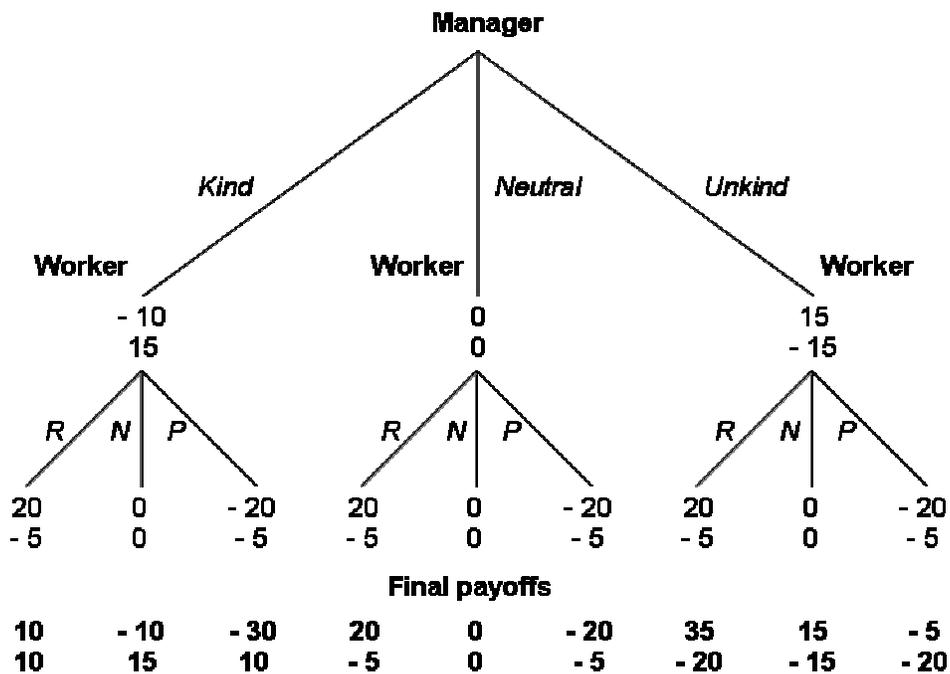

Figure 1: Stage game

In each column vector, top number is manager payoff, bottom number is worker payoff. Final payoffs are obtained by summing the each of the two vectors implied by the strategy. *R* denotes reward, *N* denotes neutral and *P* denotes punishment.

At all nodes, if the worker plays *neutral*, both players' payoffs are unchanged. If the worker plays *reward*, she loses 5 points and the manager gains 20 points. If the worker plays *punish*, she loses 5 points and the manager loses 20 points. Thus *reward* and *punish* are equally costly to the worker and have symmetric effects on the manager's payoff (as in Offerman (2002)). Similar to most versions of the trust game, the unique subgame perfect equilibrium (assuming selfish preferences) is for the worker to

³ In the experiment, roles and strategies were given neutral names. See below for more details.

play *neutral* at all nodes and the manager to therefore play *unkind*. The unique symmetric efficient outcome is (*kind, reward if kind*).

2. Experimental game and treatments

The full game has 8 players: 3 managers and 5 workers. It is repeated for an uncertain number of periods. Throughout all versions of the game, the 3 managers have fixed IDs. In the key “reputation” treatment, workers also have fixed IDs, which are carried from period to period. In the one-shot, baseline treatment, the same fixed selection of IDs is randomly reassigned to each of the workers every round. For example, worker 3 might be a different person in round 1 to worker 3 in round 2. These features are common knowledge.

Play proceeds in the following manner.

1. Nature decides the order in which each manager gets to select the worker that will be her partner (uniform distribution).
2. The first manager selects her partner; the next manager selects from the remaining workers, and so on.
 - The 2 workers who are unselected for the round lose 25 points. This is 10 points less than the worst guaranteed payoff when selected. In other words, being employed by a nasty manager is better than being unemployed.
3. Each manager chooses between *kind*, *neutral* and *unkind*.
4. Each worker finds out which manager selected them and what choice the manager made. The workers who were not selected are informed of these choices.
5. Each paired worker chooses between *reward*, *neutral* and *punish*.
6. All players see their own payoffs for the round. They also see the choices made by all manager-worker pairs in that round and they see the history of choices by all pairs.
 - Recall that worker IDs are only fixed in the reputation treatment. In the one-shot treatment, it is common knowledge that, say, worker 5’s choice in round 3 may not have been made by the same player as worker 5’s choice in round 4.

The game is repeated for a total of 11 rounds, though at the start of the experiment to prevent end-game effects subjects are told only that the experiment will continue for a “number of rounds.” Moreover, the decision-making stages of all sessions end at least 25 minutes in advance of the 90 minutes for which subjects sign up (it takes about 10 minutes to calculate earnings and pay subjects).

The reputation treatment is designed to capture a situation where reputational concerns – allied with an exclusion threat – will make positive reciprocity dominate negative reciprocity. The one-shot treatment is designed as a control where the elimination of reputational concerns and strategic exclusion will move the balance back towards the stylized fact, i.e., dominance of negative reciprocity.

To explore affective reactions, in some sessions we asked each paired worker to declare privately how they feel about their manager’s choice: *very unhappy*, *somewhat unhappy*, *neutral*, *somewhat happy*,

very happy.⁴ This permits an exploration of whether affective reactions have a greater influence on reward/punishment decisions in the one-shot treatment. Since worker behavior was not different across the sessions where this information was elicited, we pool the data below.

3. Procedure

In total, we ran 9 sessions at George Mason University during spring 2009. Subjects were recruited from a database of students who had declared an interest in participating in economics experiments. Each session had 11 periods and 16 subjects divided into two groups of 8 (3 managers, 5 workers). Roles were assigned randomly and all interactions were anonymous. Subjects' roles were fixed and they interacted exclusively with members of their own group. The total number of worker observations collected is therefore 591.⁵

The experiment was computer-based and used z-Tree (Fischbacher (2007)). Instructions were on-screen, though a hard copy was given to each subject. All subjects were in the same room and within earshot and eyeshot of each other. This is potentially important because the monitor read the instructions aloud to ensure common knowledge. The game was presented in a neutral frame, i.e., managers chose between *left*, *middle* and *right*, and workers chose between *add 20*, *nothing* and *subtract 20*. Managers were called *Reds* and workers were called *Blues*. After completing the experiment, subjects were paid privately.⁶

3. Empirical results

Table 1 presents a summary of the experimental results. In this summary, to provide a first glimpse of behavioral patterns we have ignored data dependencies and pooled individual play over all 11 periods of the game. As we discuss each result below, we supplement these raw data patterns with conditional analysis. We begin with a first result.

Result 1: In both treatments, workers reciprocate manager choices: they frequently reward *kind* and punish *unkind*.

Evidence to support this result can be seen in Table 1, where it is shown that workers reward *kind* actions in 51% of the cases in the one-shot treatments and in 84% of the cases in the reputation

⁴ The only part of the game that was not common knowledge was asking about emotions; it was not read out at the start (see procedure below) and only appeared on the workers' screens. This was done to minimize priming of the subjects to think in terms of affective reactions. As noted, for robustness we also ran sessions where we did not ask the workers to declare their emotions. None of the results were affected.

⁵ The treatment breakdown was 396 from one-shot and 195 from reputation. We lost the data from the last period of one group in one session (3 observations).

⁶ To compensate for the fact that some subjects had a negative payoff, there was a large show-up fee, though this was only announced after the start of the experiment, i.e., subject recruitment utilized the usual GMU show-up fee. Average earnings were approximately \$18.

treatment. Likewise, they punish *unkind* actions in 53% of the instances they occur in the one-shot treatment and in 34% of the instances they occur in the reputation treatments.⁷ These figures are both significantly higher than the propensities to react positively or negatively to other manager actions (i.e., the percentage of reward play in response to a manager choosing *neutral*), and are all significantly different from zero using conventional parametric statistical tests at the $p < 1\%$ level. Similar results are found when using nonparametric tests that have a null hypothesis of no treatment effect, or that the two samples are derived from identical populations.

	One-shot	Reputation
Number of sessions	6	3
Relative frequency of <i>Kind</i>	36%	43%
Relative frequency of <i>Unkind</i>	54%	51%
Relative frequency of rewarding <i>Kind</i>	51%	84%
Relative frequency of punishing <i>Unkind</i>	53%	34%
Average emotion given <i>Kind</i>	1.7	1.8
Average emotion given <i>Unkind</i>	-1.6	-1.4
Relative frequency of reselection if rewarded <i>Kind last period</i>	69%	91%
Relative frequency of reselection if did not reward <i>Kind last period</i>	64%	54%
Relative frequency of reselection if punished <i>Unkind last period</i>	56%	37%
Relative frequency of reselection if did not punish <i>Unkind last period</i>	61%	61%

Table 1: Summary statistics by treatment

Emotions are scaled as follows: -2 = very unhappy, -1 = somewhat unhappy, 0 = neutral, +1 = somewhat happy, +2 = very happy.

⁷ All of our inference (for all the results) excludes the data corresponding to managers selecting *neutral* since it is not relevant to comparisons of positive and negative reciprocity. For the interested reader, here are a few features of the excluded data. Managers play *neutral* 8% of the time. In both treatments, worker emotions in response to *neutral* are insignificantly different from 0 (on a scale of -2 to +2) using a t-test ($p > 30\%$).

These unconditional tests treat observations as IID. As a robustness check, we estimate conditional parametric models that include period and group fixed-effects as well as individual clusters.⁸ The conditional results echo the unconditional results. For parsimony, we relegate them to the appendix.

This result is not surprising, as scores of studies have found reciprocal behavior – from student subjects to CEOs (see, e.g., Offerman (2002), Andreoni et al. (2003), Fehr and List (2004)). Examining the data at a slightly deeper level, we observe another result that is in line with the literature.

Result 2: In the one-shot treatment, negative reciprocity is slightly stronger than positive reciprocity, though the difference is statistically insignificant.

Evidence to support this result can be seen in Tables 1 and 2. In Table 1, for example, we find that in the one-shot treatment, workers reward *kind* actions in 51% of cases, while they punish *unkind* at the slightly higher rate of 53% of cases, though this difference is insignificant using Mann-Whitney and t-tests.

In Table 2, we demonstrate this result using conditional tests with individual clusters. Let the outcome variable be a dummy variable taking the value ‘1’ if a worker reciprocates, i.e., responds to *kind* with *reward* or responds to *unkind* with *punish*. We denote this variable *reciprocate*. Let the control group be the observations where the manager plays *unkind* and let the treatment group be the observations where the manager plays *kind* (both in the one-shot sessions).

The estimated coefficient on ‘positive reciprocity’ should be read as how much more likely a worker is to reward *kind* than she is to punish *unkind*. Using both a linear probability model (model 1) and a probit model (model 2), punishing *unkind* is 9% more likely than rewarding *kind*, though this difference is again insignificant ($p = 31\%$). This is directionally consistent with the existing literature’s finding that in one-shot environments, the negative reciprocity is stronger than positive reciprocity (Offerman (2002), Al-Ubaydli and Lee (2009)).⁹ Our next result departs from the existing literature.

Result 3: In the reputation treatment, positive reciprocity is stronger than negative reciprocity.

Evidence to support this result can be seen in Tables 1 and 2. Looking at Table 1, we see that in the reputation treatment, unconditionally, a worker is 50% more likely to reward *kind* than she is to punish *unkind*. Both Mann-Whitney and t-tests are significant at conventional levels ($p < 1\%$).

The conditional results with individual clusters are contained in Table 2. Again, the estimated coefficient on ‘positive reciprocity’ should be interpreted as how much more likely a worker is to reward *kind* than she is to punish *unkind*. Using both a linear probability model (model 3) and a probit model (model 4), we find that the estimated coefficient is over 50% and statistically significant ($p < 1\%$).

⁸ In all our parametric models, we use *two* clusters per worker: one for the worker’s decision at the *kind* node and one at the *unkind* node. Using a common cluster instead affects none of our results (in fact using a common cluster shrinks the standard errors – as one would expect – though not by enough to alter any result).

⁹ Essentially all our results are robust to using only data from periods 6-to-11, reinforcing the design’s attempts at avoiding any ‘end-of-session’ effects. The only slight exception is result 4. See below.

	Model 1	Model 2	Model 3	Model 4	Model 5	Model 6	Model 7	Model 8	Model 9	Model 10	Model 11
<i>Estimation method</i>	Regression	Probit	Regression	Probit	Regression	Probit	Regression	Regression	Probit	Regression	Probit

Table 2: Conditional results

The dummy variable ‘Reciprocate’ takes the value 1 when the worker reciprocates *kind* with *reward* or *unkind* with *punish*. Emotions are scaled as follows: -2 = very unhappy, -1 = somewhat unhappy, 0 = neutral, +1 = somewhat happy, +2 = very happy. The dummy variable ‘Reselect’ takes the value 1 when a worker is reselected by (any) manager in that period given selection in the previous period. ‘Positive reciprocity’ is a dummy variable that takes the value 0 when the manager plays *unkind* and 1 when the manager plays *kind*. ‘Reputation session’ is a dummy that takes the value 1 in reputation sessions. In probits, the reported figure is the estimated marginal effect. All models contain clusters at the individual level. Group effects correspond to the fact that each session has two groups. All models exclude the 49 observations corresponding to the manager playing *neutral*. Estimated period/group fixed effects are omitted. Asterics denote statistical significance (* = 10%, ** = 5%, *** = 1%).

This result stands in stark contrast to results in the literature, and questions the generality of bad being stronger than good. And, it provides the empirical reversal that has alluded researchers who have been unable to locate such an example (Baumeister et al. (2001)). Results 4-to-6 attempt to shed light on the underpinnings for this reversal.

Result 4: The difference in reciprocity between one-shot and reputation sessions is driven primarily by a large increase in positive reciprocity when going from one-shot to reputation sessions.

Empirical evidence to support this result can be seen in Table 1, where positive reciprocity increases by 34% when moving from the one-shot to the reputation treatment, whereas punishment falls by 19%. Testing this formally requires a conditional parametric specification. In models 5 and 6 in Table 2, we pool the data from our one-shot and reputation treatments and include a reputation by session dummy variable and an interaction term between positive reciprocity and the reputation by session dummy.

The reputation by session dummy coefficient informs tells us how much more likely workers are to punish *unkind* in the reputation treatment than in the one-shot treatment. The point estimates, of roughly 20%, suggest that workers are substantially less likely to punish in the reputation treatment, though this is not statistically significant at conventional levels. Thus negative reciprocity is at most slightly smaller in the reputation treatment than in the one-shot treatment.

Given this result, the large (greater than 46%) and significant ($p < 1\%$) coefficient of the interaction of the reputation and positive reciprocity is primarily the result of a substantial increase in positive reciprocity when going from one-shot to reputation.¹⁰ Our next result concerns the underpinnings of the reversal.

Result 5: The difference in the balance of positive and negative reciprocity across one-shot and reputation sessions is not the result of differences in the affective reactions to *kind* and *unkind* across one-shot and reputation sessions.

Evidence to support this result can be seen in Tables 1 and 2. Recall that the scale for worker's declared emotion after seeing the manager's choice is: -2 = very unhappy, -1 = somewhat unhappy, 0 = neutral, +1 = somewhat happy, +2 = very happy.

In Table 1, the mean emotion in response to *kind* is +1.7 in the one-shot treatment and +1.8 in the reputation treatment. This difference is insignificant using three unconditional tests (Mann-Whitney: $p = 19\%$, t-test: $p = 30\%$; Kolmogorov-Smirnov: $p = 96\%$). The mean emotion in response to *unkind* is -1.6 in the one-shot treatment and -1.4 in the reputation treatment. This difference is marginally significant or insignificant depending on the unconditional test employed (Mann-Whitney: $p = 10\%$, t-test: $p = 12\%$; Kolmogorov-Smirnov: $p = 66\%$).

In model 7 in Table 2, we estimate a regression model of emotions (with individual clusters) on three explanatory variables: 'positive reciprocity,' which takes the value 0 when the manager has played

¹⁰ When we only use data from periods 6-to-11, in addition to the large increase in reward (73%), there is a large (but still smaller) decrease in punishment (52%). This does not affect the paper's main argument.

unkind and 1 when the manager has played *kind*; a reputation session dummy; and an interaction between these two variables. In this model, the estimated coefficients on the reputation sessions dummy and on the interaction between positive reciprocity and reputation sessions dummies are statistically insignificant. In other words: worker emotive responses to manager choices do not depend upon being in one-shot vs. reputation treatments. Thus, the marginal significance levels obtained in a couple of the unconditional tests are the result of erroneously treating the observations as IID.¹¹

Perhaps the most compelling evidence that the results are not driven by differences in affective reactions is that in the one-shot sessions, when the worker was very unhappy at the manager playing *unkind*, she rewarded the manager 3% of the time. The corresponding Figure for the reputation sessions was 17% (n = 103, p < 5% using a t-test and a MW-test). Clearly several workers were willing to reciprocate due to the threat of strategic exclusion in the reputation sessions.

This suggests that the difference in the balance of positive and negative reciprocity across one-shot and reputation sessions is not the result of differences in the affective reactions, leading to our next result.

Result 6: The difference in the balance of positive and negative reciprocity across one-shot and reputation sessions is the result of strategic differences in the environment, specifically the threat of systematic exclusion.

Evidence to support this result can be seen in Tables 1 and 2. The dimensionality of the history space is too large for sophisticated structural modeling (the data demands are not met either), however result 6 can still be derived from a more modest structural approach. The basic hypothesis is that in the reputation sessions, managers seek workers who have rewarded *kind* or who did not punish *unkind*.

In Table 1, for example, we see that in the reputation treatment, if a worker rewards a play of *kind*, then this increases her chances of being reselected by a manager in the subsequent round by 43% compared to not rewarding (significant at p < 3% using Mann-Whitney and t-tests). Similarly, if a worker punishes a play if *unkind*, then this decreases her chances of being reselected by a manager in the subsequent round by 24% compared to not punishing (significant at p < 3% using Mann-Whitney and t-tests). In the one-shot treatments, statistically speaking, reselection chances are unaffected by past play. This is comforting since the worker IDs were scrambled every round and so the managers could not perform any systematic exclusion.

Table 2 reveals that conditional models with individual clusters yield consistent results. Models 8 and 9 confirm that rewarding *kind* increases a worker's probability of being selected in the next round by over 35%. On the negative reciprocity side, models 10 and 11 confirm that punishing *unkind* diminishes a worker's probability of being reselected by over 24%. Again, re-estimating models 8-11 using data from the one-shot sessions (omitted for parsimony), we find that all coefficients are statistically insignificant (all have a p-value greater than 50%) and have very small magnitudes (smaller than 5%).

¹¹ A minor result that we omit for parsimony is that in both treatments, emotions predict reward and punishment in the expected way, i.e., subjects who report more positive emotions are more likely to reward and less likely to punish.

While it is clear that managers account for worker actions in their partnership choices, another manner in which managers' behavior potentially changes is due to treatment itself. Our data reveal that workers punish much less often but reward more frequently in the repeated game than in the one shot game. An interesting query is whether managers use this information effectively in their choices.

Given the unconditional relative frequencies of reward and punishment behavior in the one-shot treatment, and treating workers choices as IID draws, then for managers we have that *unkind* \succ *kind* \succ *neutral*, where \succ denotes strict preference under expected-payoff maximization. This is loosely reflected in their choices (see Table 1): *unkind* (54%), *kind* (36%), *neutral* (9%). The comparatively large incidence of *kind* is consonant with equity considerations.

In the reputation treatment, both the optimal and realized rank-ordering of manager choices is unchanged. While there is a slight increase (7%) in *kind* at the expense of *neutral* and *unkind*, none of the changes are statistically significant using conditional or unconditional tests. To some extent, this is unsurprising since increased reward and decreased punishment renders *kind* and *unkind* simultaneously more lucrative in absolute terms. This exploration leads to our final result.

Result 7: Efficiency is substantially higher in the reputation treatment.

The total realized payoff in the one-shot treatment is 14% of the total potential payoff, while the corresponding Figure for the reputation treatment is 40%. The reason why both are so low is because any deviation from *kind* and reward leads to a lower aggregate payoff, and such deviations are very frequent. Naturally, the efficiency improvement is driven by workers moving away from punishment towards reward.

4. Conclusion

As Arrow (1972, p. 357) put forth decades ago when he noted that "Virtually every commercial transaction has within itself an element of trust," most economic and non-economic transactions require a degree of trust. With the element of trust comes the necessary ingredient reciprocity. Scholars as far back as Aristotle (2004) appreciated the importance of negative reciprocity, as he extolled that revenge serves to discourage mistreatment. More recently, scientists have come to the firm conclusion that both negative and positive reciprocity are important, but that at a general level the relative strengths are not comparable: bad is stronger than good.

This paper revisits this stylized fact by infusing two realistic features – the agent is on the short end of a market that includes reputational considerations and that being out of the market provides less utility than being a participant – into a popular laboratory game. We argue that these additional considerations provide a setting that is representative of many common economic situations. This alteration permits us to examine the relative strengths of positive and negative reciprocity while simultaneously exploring the underpinnings for reciprocity.

We find that the stylized fact in the literature is reversed in our setting: in repeated environments with a threat of systematic exclusion, good is stronger than bad.¹² This holds because in our setting being employed by an exploitative manager dominates unemployment. Rational agents understand that this is the case and act accordingly. Importantly, this reversal is not the consequence of a change in affective reactions. People are as happy about kind behavior in the repeated environment as they are in the one-shot environment, and they are equally riled by unkind behavior across the two environments. Rather, the prominence of positive reciprocity in the repeated environment is driven by strategic concerns: those workers who are cooperative – either by reciprocating kind behavior or refraining from punishing unkind behavior – avoid unemployment by acting appropriately in the environment.

We view these results as important in several domains. First, they move us toward a deeper understanding of the relative strengths of positive and negative reciprocity. In this way, the received results highlight the importance of the economic and psychological features embedded in any economic environment. Second, in doing so they open new paths of inquiry. For instance, in public policymaking, the general discussion of whether preferences are defined over consumption levels or changes in consumption has moved policymakers to more carefully consider the differences between willingness to pay and willingness to accept in cost benefit analysis. Understanding the mechanisms that underlie these valuation divergences is invaluable. Also, the practitioner interested in mechanism design might regard the results of import when crafting incentive schemes to alter agent behavior.

Table A1: Conditional results for result 1

The dummy variable ‘Reward’ takes the value 1 when the worker rewards. The dummy variable ‘Punish’ takes the value 1 when the worker punishes. In probits, the reported figure is the estimated marginal effect. All models contain clusters at the individual level. Group effects correspond to the fact that each session has two groups. Estimated period/group fixed effects are omitted. All models exclude the 49 observations corresponding to the manager playing *neutral*. Asterices denote statistical significance (* = 10%, ** = 5%, *** = 1%).

Experimental instructions

Welcome to our experiment in decision making.

If you read these instructions carefully and make good decisions, you may earn a considerable amount of money. At the end of the experiment, your earnings will be paid to you, privately and in cash.

At the beginning of the experiment, you will be randomly separated into groups of 8. You will only interact with your group members. Three of you will be randomly assigned the role of Red and five of you the role of Blue. So there are more Blues than Reds. [NEXT]

At the beginning of the experiment, both Reds and Blues get 200 points each as a show-up fee. We will convert the points you earned into dollars at the rate of 10 points = \$1. [NEXT]

The experiment has a number of rounds. Each round has two stages.

Stage 1:

- *The Reds take turns to individually choose a Blue. The order in which the Reds get to choose a Blue is randomly determined.*
- *This results in 3 Red-Blue pairs with 2 Blues left unmatched.*
- *The 2 Blues who have not been chosen in this round do nothing and their final earnings for the round are -25 points. [NEXT]*
- *Each Red chooses LEFT, MIDDLE or RIGHT.*
 - *If a Red chooses LEFT: Red's earnings are -10 points, Blue's earnings are +15 points.*
 - *If a Red chooses MIDDLE: Red's earnings are 0 points, Blue's earnings are 0 points.*
 - *If a Red chooses RIGHT: Red's earnings are +15 points, Blue's earnings are -15 points. [NEXT]*

Stage 2:

- *Each Blue learns if they are in a pair with a Red.*
- *If they are in a pair, they will learn the action their Red partner chose among LEFT, MIDDLE and RIGHT, and the corresponding earnings in points.*
- *The paired Blues will choose 1 of 3 actions:*
 - *To add 20 points to their Red partner at the cost of 5 points to them.*
 - *To subtract 20 points from their Red partner at the cost of 5 points to them.*
 - *Do nothing at zero cost. [NEXT]*
- *Red's final earnings will be changed by their Blue partner's choice to add or subtract. If Blue chose to subtract, then Red's earnings decrease by 20 points. If Blue chose to add, then Red's earnings increase by 20 points. In both cases Blue's earnings decrease by 5 points.*
- *If Blue does nothing, then Red's and Blue's final earnings are the points initially decided by the action chosen by the Red partner.*

- Blues who have not been chosen in this round do nothing and their final earnings for the round are -25 points. [NEXT]

That's a round. The experiment will last a number of rounds. [NEXT]

Reputation treatment

IDs:

- Reds and Blues will have IDs (e.g., Red 2 or Blue 4). Both Reds and Blues always keep the same ID.
- After every round, everyone will see the actions chosen by the 3 Red-Blue pairs up to and including that round. People's action choices are labeled by their ID.

We will begin the experiment now. Your role in the experiment will be decided in the next screen. After your role is decided, I will read the specific instructions for Reds and Blues. Please refrain from asking any questions until I finish reading these instructions. [NEXT]

Your ID for this round is Red ***. Your ID will be the same for all rounds. Specific instructions for Reds:

- The order in which you choose Blues as partners may change every round.
- If you are the first, you can pick any of the 5 Blues.
- If you are not the first, then you only pick from the Blues that were not chosen before.
- The 2 Blues that are not picked will earn -25 points for that round.
- Remember: both Reds' and Blues' IDs are always the same throughout the experiment.
- After choosing a Blue counterpart for the first stage, we ask that you choose LEFT, MIDDLE or RIGHT. The corresponding earnings are shown in the supplementary Figure.
- You will find out your Blue partner's choice. [OK]

Now the Blues. Your ID for this round is Blue ***. Your ID will be the same for all rounds. Specific instructions for Blues:

- If a Red picks you in a given round, you will find out which action your partner chose. The corresponding earnings are shown in the supplementary Figure.
- Then you will choose 1 action among 3 actions
 - To add 20 points to your Red partner at the cost of 5 points.
 - To subtract 20 points from your Red Partner at the cost of 5 points.
 - Do nothing at zero cost.
- If a Red does not choose you, you will do nothing and your final earnings for this round are -25 points.
- Remember: both Reds' and Blues' IDs are always the same throughout the experiment. [OK]

One-shot treatment

IDs:

- *Reds and Blues will have IDs (e.g., Red 2 or Blue 4). Reds always keep the same ID. Blues get a random ID every round. (e.g. Blue 1 in round 1 may or may not be the same person as Blue 1 in round 2.)*
- *After every round, everyone will see the actions chosen by the 3 Red-Blue pairs up to and including that round. People's action choices are labeled by their ID.*

We will begin the experiment now. Your role in the experiment will be decided in the next screen. After your role is decided, I will read the specific instructions for Reds and Blues. Please refrain from asking any questions until I finish reading these instructions. [NEXT]

*Your ID for this round is Red ***. Your ID will be the same for all rounds. Specific instructions for Reds:*

- *The order in which you choose Blues as partners may change every round.*
- *If you are the first, you can pick any of the 5 Blues.*
- *If you are not the first, then you only pick from the Blues that were not chosen before.*
- *The 2 Blues that are not picked will earn -25 points for that round.*
- *Remember: Blues' IDs may change every round.*
- *After choosing a Blue counterpart for the first stage, we ask that you choose LEFT, MIDDLE or RIGHT. The corresponding earnings are shown in the supplementary Figure.*
- *Remember: you keep the same ID throughout the experiment.*
- *You will find out your Blue partner's choice. [OK]*

*Now the Blues. Your ID for this round is Blue ***. Your ID may change every round. Specific instructions for Blues:*

- *If a Red picks you in a given round, you will find out which action your partner chose. The corresponding earnings are shown in the supplementary Figure.*
- *Remember: your ID may change every round.*
- *Then you will choose 1 action among 3 actions*
 - *To add 20 points to your Red partner at the cost of 5 points.*
 - *To subtract 20 points from your Red Partner at the cost of 5 points.*
 - *Do nothing at zero cost.*
- *If a Red does not choose you, you will do nothing and your final earnings for this round are -25 points.*
- *Reds always keep the same ID. [OK]*

Check if there are any questions. If not, the game should start. If anyone asks about the number of rounds, the experimenter should simply repeat:

"The experiment will last a number of rounds."

The experiment should go on for 11 rounds or 70 minutes – whatever comes first. That leaves 20 minutes for paying people etc.

Sample screenshot of a manager's choice:

Round 2

Your ID for this round is **Red 1**
Your ID will be the same for all rounds.

Game History: **Red 1**

Round	Choice order	Paired with	Red action	Blue action
1	3	3	Left	+20

Game History: **Red 2**

Round	Choice order	Paired with	Red action	Blue action
1	1	1	Left	+20

Game History: **Red 3**

Round	Choice order	Paired with	Red action	Blue action
1	2	2	Left	+20

Your profits in all rounds

Round	Your Profits	Total Profits
1	10	210

Stage 1
Choose your **Blue** partner for this round.
The 2 blues that are not picked by any of the reds will earn -25 for this round

Available Blue 1
Available Blue 2
Available Blue 3
Available Blue 4
Available Blue 5

Enter your choice; Blue

OK

Sample screenshot of a worker's choice:

Round 1

Stage 2
Your ID for this round is **Blue 1**
Your ID will be the same for all rounds.

Your partner Red 3

You have been selected by a red for this round. The 2 Blues that were not selected received -25 for this round

If your partner picks:
LEFT: you get +15, your partner gets -10
MIDDLE: you get 0, your partner gets 0
RIGHT: you get -15, your partner gets +15

Action chosen LEFT

Earnings from your partner's action You get +15, your partner gets -10

Choice to add or deduct

Add 20: costs you 5
 Add/subtract 0: costs you 0
 Subtract 20: costs you 5

OK
