JEL No. D03,D44,J24,L62,M5

ABSTRACT

A large body of research has explored the importance of auction design and information structure for auction outcomes. Much less work has considered the importance of the auction process. For example, in many auctions, auctioneers are present and can impact the process of the auction by varying starting prices, level of price adjustments, the speed of the auction, the way they interact with auction participants, or their characteristic chant that is intended to excite buyers. We explore the importance of auction process by testing whether auctioneers can have a systematic difference on auction outcomes. We analyze more than 850,000 wholesale used car auctions and find large and significant differences in outcomes (probability of sale, price, and auction speed) across auctioneers. The performance heterogeneities are stable across time and correlate with subjective evaluations of auctioneers provided by the auction house. Although the available data here do not allow us to conclusively isolate mechanisms, a range of evidence suggests a role for tactics that generate excitement among bidders. Overall, these findings illustrate the complexities of auction environments and how outcomes can be impacted by subtle changes in process.

1. Introduction

Auctions are central features of many markets, including those for radio spectrums, used industrial machinery, livestock, used cars, antiques, government-owned property, procurement, debt instruments, charity, and real estate. It is therefore not surprising that economists have developed a large body of research on the functioning of auctions, including theoretical, experimental, and empirical studies. Much of this work has focused on exploring the effects of different auction structures, comparing common designs such as English, Dutch, first-price sealed-bid, and second-price auctions, and assessing their revenue generation and efficiency. The literature has paid particular attention to how the performance of different auction designs may depend on the underlying distributions of product valuations and the level of information available to market participants.¹

Although a large literature has explored the importance of auction structure to outcomes, the process of running an auction (conditional on the auction design) has received much less attention. As some auction theorists have noted (Klemperer, 2002; Milgrom, 2004), many auctions involve human participants who may be misinformed or boundedly rational in some way. In these settings, the details associated with how an auction is run may significantly influence outcomes.

An example of how auction process may vary from one auction to another is the leeway that a live auctioneer has in choosing how to run an ascending-bid auction. Theoretical models of auctions largely abstract from the role of the auctioneer in the auction process. In particular, Milgrom and Weber (1982) modeled English auctions assuming that prices rise continuously from a low level and that all participants hold down a button and can be observed dropping out of the auction at some point when the price rises too high. Within that structure, there is no role for an auctioneer and the focus naturally becomes on the information structure (e.g., private signals) of the bidders in the auction. But as Milgrom and Weber themselves highlight, many real-world ascending-bid auctions involve human auctioneers who are typically experienced professionals. These auctioneers may influence the process of an auction by choosing opening bid amounts, changing the pace of price adjustment, and deciding when to stop the bidding. In addition, many auctioneers (especially in the U.S.) interact with bidders and call out bids in a fast-paced, rhythmic chant, attempting to create a sense of urgency and excitement among bidders.

In this paper, we explore whether these real-world details of the auction process are important for understanding auction outcomes by studying whether auctioneers have a systematic impact on auction outcomes. Although the impact of single individuals on organizational outcomes has been explored in

¹ An overview of auction theory can be found in Bulow and Roberts (1989), Klemperer (2004), and Milgrom (2004).

other contexts (e.g. CEOs and bosses, judges, teachers, scientists, and political leaders),² there has been no systematic empirical analysis of the impact of auctioneers on relevant outcomes.³ We investigate this question in the context of wholesale, used-car auctions. This market is well suited to studying the role of auctioneers for several reasons. First, these are large markets – more than 10 million used cars are traded in the U.S. at wholesale auctions each year (Manheim, 2011), totaling over \$80 billion in sales (NAAA, 2009). Second, because both buyers and sellers are professionals and because these cars are high-value goods, we expect all participants to have strong incentives. Third, as we will argue below, the institutional features and data available allow us to capture the causal impact of individual auctioneers on prices, the probability of sale, and other performance measures. Finally, the structure of these auctions is an ascending auction (English-style) with a live auctioneer and no pre-determined time limit. There is a large literature on English-style auctions that has to date made a great deal of traction while abstracting from the details of auction process. Authors, such as Cassady (1967) have argued, however, that this is the format in which the auctioneer has the most potential to influence the sale, and as such English auctions and the role of auctioneers would seem a good place to begin to more systematically study the importance of the details of how auctions are conducted.

Our data include over 850,000 cars auctioned by 60 auctioneers between 2007 and 2013 at the largest location of a leading operator of used-car auctions in the U.S. The primary measure of auctioneer performance we analyze is each auctioneer’s conversion rate (the fraction of cars that end in a sale). The auction company and its auctioneers make it clear that the primary role of the auctioneer in this context is to maximize the probability of each car selling. We also study two secondary performance metrics: residual price (the difference between sales price and average market value) and speed of sale.

An obvious threat to the identification of auctioneer heterogeneity is that cars are not randomly assigned to auctioneers. We discuss identification assumptions in detail below and argue that non-random selection can be accounted for by controlling for important features of the auction (auction day, seller of the car, car type, etc.). We also provide additional tests which include exploiting shift changes as a way to identify the causal impact of auctioneers on outcomes.

We find significant dispersion in auctioneers’ fixed effects in each of the three performance measures. In our preferred specification, a one-standard deviation increase in auctioneer performance corresponds to

² See, for example, Abrams, Bertrand and Mullainathan (2013); Azoulay, Graff Zivin and Wang (2010); Bertrand and Schoar (2003); Chetty, Friedman, Hilger, and Saez (2010); Hanushek (2011); Jones and Olken (2005); Lazear, Shaw, and Stanton (2012); Malmendier and Tate (2009).

³ To our knowledge, the only two studies examining auctioneers are Capizzani (2008), who presented experimental evidence regarding the presence of a live auctioneer whose only role was to choose the public-information structure, and Cassady (1967), who provided a detailed qualitative description of auctions and auctioneers. Note, moreover, that much of the literature uses the term “auctioneer” to refer to the auction house or platform (Hossain, Khali, and Shum, 2013), or, in some cases, the seller. In this paper we reserve the term auctioneer strictly for the person calling out bids at a live auction, and the term seller strictly for the owner of the car who brings it to the auction house.

an increase in the probability of sale by 2.3 percentage points (the average sales probability is 53%), an increase in residual sales price by \$41.8 (the average sales price is \$15,141), and an increase in speed of sale by 6.1 seconds (the average length of sale is 103 seconds). We apply an Empirical Bayes shrinkage correction to account for the fact that each auctioneer's effect is noisily measured and find that the estimated effects in general change very little, suggesting that the heterogeneity that we find is not merely due to natural sampling variation. The performance enhancements in conversion rates due to higher-ability auctioneers are generally comparable to those found in studies that estimate the effects of changes in auction design, information structure, and broader macroeconomic factors on similar outcomes (Coe, Larsen and Sweeney, 2013; Hortacsu, Matvos, Syverson, and Venkataraman., 2013; Tadelis and Zettelmeyer, 2011). Additionally, the improvements in price are comparable to the theoretical benchmarks of designing the auction optimally or of including an additional bidder given by Bulow and Klemperer (1996).

A number of additional analyses and robustness checks support our findings that some auctioneers indeed outperform others. First, the performance heterogeneity for conversion rates and time on the block is persistent over time: on average, auctioneers who achieved higher conversion rates or faster sales in the first half of our sample (2007-2009) also performed better in the second half (2010-2013). Second, the different performance metrics are correlated at the individual level in that auctioneers with higher conversion rates also achieve higher prices and are typically faster. We also find that these objective performance metrics are correlated with subjective evaluations of auctioneers that were made available to us by the auction house. Our metrics are also predictive of which auctioneers left the company during a period of downsizing.

These results suggest that the way an auction is run can have a nontrivial impact on outcomes, and in particular, human auctioneers do not simply call out prices and recognize bids. It is also important to bear in mind that these wholesale auto auction environments involve large stakes and are conducted with professionals who often have substantial auction experience. To us this suggests that auctioneer effects are not a quirk related to unfamiliarity with auctions, but rather a fundamental feature of well-established and well-functioning auction environments. The fact that we observe substantial heterogeneity across a pool of professional auctioneers also suggests that auction houses have not found ways to transfer these successful practices throughout their auctions.

Having documented that auctioneers vary systematically in their effects on auction outcomes, a natural next step is to explore the mechanisms at play in generating these differences. Deeper explorations of specific auction processes should be an interesting avenue for a whole body of future research and we suspect that experimental methods are likely to be the best avenue for exploring these issues. As a first step to better understanding the mechanisms at play in auctioneer success, we lay out five classes of

potential mechanisms. We consider the possibility that auctioneers differ in their ability to 1) convey information about car quality, 2) convince sellers to lower their reservation values and accept auction outcomes, 3) generate patterns of bids that reveal more information about the range of bidder valuations, 4) help reduce search frictions and match buyers to appropriate cars, and 5) exploit behavioral biases related to issues such as excitement in auctions. These mechanisms are difficult to disentangle, because they are not mutually exclusive and frequently observationally equivalent. Nonetheless, we present qualitative evidence from surveys with auctioneers and also discuss patterns in our data that provide suggestive evidence about these mechanisms. We can conclude with relative certainty that auctioneers in this setting do not convey information about the quality of cars, and we also find little support for the idea that they are primarily trying to persuade sellers to lower their reservation values. We have less conclusive results about the other mechanisms that relate to changing buyer values, but the evidence supports the idea that part of the difference in auctioneer abilities arises because some auctioneers are better at creating excitement and competitive arousal among buyers. In particular, industry participants often report that successful auctioneers use speed and pacing of auctions to affect the level of excitement in ways that increase bidding, and that specific mechanism appears to be consistent with our findings that auctioneers who run faster-paced auctions are somewhat more likely to achieve sales and higher prices.

In showing suggestive evidence that auctioneer heterogeneity resides at least in part in the ability to generate excitement among bidders, this paper contributes to a small but growing literature exploring behavioral factors in auction environments such as auction fever or overbidding (Ockenfels, Reiley, and Sadrieh, 2007; Podwol and Schneider, 2011; Malmendier and Szeidl, 2008). In the literature, auction fever—also referred to as competitive arousal or bidding frenzy—encompasses many behaviors, such as rivalry or spite (Morgan, Steiglitz, and Reis, 2003; Ku, Malhorta, and Murnigham, 2005; Cooper and Fang, 2008); endowment effects (Heyman, Orhun, and Ariely, 2004; Dodonova and Khoroshilov, 2009); utility of winning (Cooper and Fang, 2008); regret/fear of losing (Cramton, Filiz-Ozbay, Ozbay, and Sujarittanonta, 2012; Filiz-Ozbay and Ozbay, 2007); uniqueness of being first (Ku, Malhorta, and Murnigham, 2005); and irrational limited attention (Lee and Malmendier, 2011). Documenting the relevance of behavioral factors in auctions is particularly relevant in our context where actors are informed professionals, as in Goldreich (2004). Our evidence is also related to work in psychology, for example, suggesting that thought speed can have an impact on mood (Pronin and Wegner, 2006). Ku, Malhorta, and Murnigham (2005) also studied how time pressure can affect bidding, and Malhorta (2010) found, in a field experiment, that the combination of rivalry effects and time pressure is particularly strong in leading to additional bidding.

The results here also provide new insights about how these complex auction interactions unfold. This can inform auction design theory on how specific auction processes may affect, for example, revenue

equivalence and the strategic equivalence among auction structures. We suggest that there are important dynamics at play in English auctions that are not captured by the classic framework and as such point to the importance of existing work on expanding models (Harstad and Rothkopf, 2000) and econometric approaches (Haile and Tamer, 2003) to account for the richness of real auction environments.

The rest of the paper proceeds as follows. Section 2 discusses the data and offers detail on the institutional context. The empirical strategy and our main results are reported and discussed in Section 3. Section 4 is dedicated to exploring the mechanisms behind the heterogeneity across auctioneers. Finally, Section 5 offers concluding remarks.

2. Institutional Details and Data

The company for which we have data specializes in providing auction services for the wholesale used car market. This company has many auction facilities around the U.S., where each facility holds an auction typically once or twice per week. Bidders at these auctions are licensed used-car dealers who typically plan to sell the cars they purchase on their personal used-car lots. The cars being sold come from two basic sources: “dealer” sellers and “fleet/lease” sellers. The dealer sales are cars being sold by retail car dealers and are primarily cars which were received as trade-ins that the dealer did not want to sell on his or her own lot. The fleet/lease sales represent cars sold by rental car companies, leasing companies, or company fleets and are typically sold in large volumes with low reservation prices. On an auction day, cars run through one of multiple lanes which operate simultaneously. The buyers bid for cars in a standard ascending-price (i.e., English) auction which typically lasts between one and two minutes. The highest bidder receives the car as long as the auction price exceeds the seller’s secret reserve price. The high bidder can personally take it back to his or her used-car lot or arrange delivery through independent agencies which operate at the auctions.

Wholesale used car auctions are conducted by professional auctioneers. Most of them have some formal auctioneer training from one of many auctioneer schools located nationwide, the existence of which is by itself suggestive that auctioneer skills and training may matter.⁴ Auctioneers also tend to learn the trade through an apprenticeship system and many come from families with long histories as auctioneers. Top auctioneers in the profession are granted awards.⁵ Section 4 discusses the characteristics and tools of an auctioneer that are considered important.

The auctioneers at the locations we study here work as independent contractors and receive a fixed daily wage for each auction day they work. The auction house periodically uses small bonus incentives

⁴ The National Auctioneers Association website (www.auctioneers.org) lists 29 schools, and additional schools are listed elsewhere.

⁵ For example, the World Auto Auctioneer Championship has been held annually since 1989.

tioned to targets like the fraction of cars sold on a lane per day. The auctioneers, however, have no commission incentives on any particular car they auction. The auction house tells us they use this compensation design in part so that the auctioneers are not seen by the bidders as agents of the seller, but rather as independent market makers.

On the auction day the auctioneers are assigned to specific lanes. There are separate lanes for dealer sales and for fleet/lease sales. Many of the fleet/lease lanes are dominated by large corporate sellers and it is easily possible for a particular fleet/lease seller to command an entire lane on some auction days. Because the fleet/lease sellers bring large volumes of cars to the auction, they are typically given preferential treatment by the auction house. Of relevance for our study, the fleet/lease sellers can either bring their own auctioneer, or often use the same auctioneer that is provided by the company week after week. In contrast, dealers tend to sell cars in smaller volumes. Typically, dealer lanes are filled on a first-come, first-served basis and the auction house will simultaneously run multiple lanes of dealer-car auctions. For example, a dealer may bring in five cars the day before the auction and be slotted into lane 15, with run numbers 26-30; another dealer may then arrive with three cars and be given run numbers 31-33 in lane 15. On average, 200-300 cars are auctioned off in each lane in a given day. The median seller in a lane on a given day represents only 6.4% of cars being auctioned in that lane on that day.

Although the method for assigning dealer cars to lanes produces a large amount of random variation in what cars an auctioneer will end up auctioning, the process is not entirely random. For example, larger dealers can often influence the choice of lane, timing of their run through the lane, or even which auctioneer is assigned to their lane.⁶ For this reason, it is important that we control for features of a car (e.g. seller effects) in our empirical strategy. We will argue that the allocation of cars to auctioneers is conditionally random after controlling for a set of important car characteristics and provide several robustness checks to help assess this identifying assumption.

We have access to information on all cars auctioned between January 2007 and June 2013 at the largest facility operated by the auction company for which we have data. For reasons provided above, we drop fleet/lease cars and focus on cars being sold by dealers in these auctions.⁷ We take several additional steps to clean the data before running analyses. We drop a small number of observations with missing data or nonsensical values. We exclude observations having outlier values on our key variables (e.g. cars that sold for less than \$100 or for more than \$75,000). We then restrict the sample to auctions conducted on two specific days of the week (there are occasionally small specialty auctions conducted on other days

⁶ In written correspondence with the general manager of the auction facility for which we have data, we asked whether auctioneers are randomly assigned to the dealer lanes. The response was, "Sometimes it is by dealer request. We try and discourage that, because we want 40 great auctioneers..."

⁷ Because the fleet/lease companies bring their own auctioneer or often have the same company-provided auctioneer every week, we have very limited variation in auctioneer assignment within a seller for fleet/lease cars.

of the week). We eliminate rerun auctions.⁸ Lastly, we reduce the sample to the 60 auctioneers who auctioned off at least 5,000 cars during our sample period. This limits the sample of auctioneers to those that worked “full time” for at least a year or two during our sample period. Within these remaining 60 auctioneers, the median auctioneer performed just over 13,000 auctions during our sample period while the busiest auctioneer performed approximately 30,000 auctions.

Our final dataset contains information on 859,239 cars. For each car we observe the make, model, body style, model year, date and time at which it was auctioned, and odometer mileage as well as an identifier for the seller of the car. We also observe whether the car sold, the sales price, the amount of time spent auctioning off the car, and the lane in which the car was sold. Lastly, auctioneer identifiers let us detect the specific auctioneer who was on the block in a given lane for a given car.⁹

Table 1 reports some basic descriptive statistics on our sample of used cars. The average car is 4.4 years old and has about 56,000 miles. About 53% of cars sell;¹⁰ in the cases when the car does not sell, the owner may take it back to his or her dealership or to a competing auction house and attempt to sell it there; or he may choose to auction the car again at an upcoming auction. The mean sales price for sold cars is slightly above \$15,000, and on average car auctions last 1 minute and 43 seconds.¹¹

We consider three main performance measures for auctioneers: a) conversion rates (fraction of cars that sold); b) the price of cars conditional on selling, and c) the time that each car is on the block. In addition to their immediate economic rationale, conversion rates and price are important to the auction company because it earns commission fees based on a car selling. It is also seen as important to retain sellers, particularly large ones, to ensure volume at the auctions; as such, selling cars at somewhat higher prices is a positive outcome. However, the company also needs to attract buyers, therefore high prices, in and of themselves, are not the company’s primary goal. The speed at which a car is sold is also of interest to the auction house as faster sales imply more cars can get through the lanes of the auction house on a given day as opposed to remaining unsold in inventory to be sold at a later date.

⁸ If a car does not sell, sometimes it will be put through the lane one more time at the end of the day with a group of other cars that did not sell. We restrict the sample to the first time a car went through the lane on a given day.

⁹ At some auctions, there is also a “ringman” on the floor of the auction who assists the auctioneer in identifying bids and energizing the crowd. The auction facility for which we have data does not use a ringman.

¹⁰ Sellers either provide the auction house with a reservation price ahead of time or, more frequently, they sit by the auctioneer during the auction of their cars. Thus, the seller often makes a decision on the block as to whether or not the highest bid is more than their reservation price. We unfortunately do not have any consistent data for the reservation prices set by sellers.

¹¹ Time on the block is calculated by subtracting the starting time stamps from consecutive car auctions on each auction lane to determine the duration of each auction. It has a smaller number of observations than the other variables because we set time on the block equal to missing if the time taken to sell the car is in the bottom or top 5 percentile. The reason we make this restriction is because it is common for a car to take a very long (or short) time to sell for factors outside of the control of the auctioneer. For example, waiting for the seller, getting the information coded into the computer, or waiting for the next car to be driven into the lane can cause an auction to last much longer than normal.

We specifically discussed these three measures with the general manager of the auction facility for which we have data. It is clear that conversion rate is the most important objective to them.¹² The general manager wrote, “Conversion rate pays the bills. Sales price and speed are generally the parents of conversion rate.” The manager indicated that as long as a car sells, the company is somewhat indifferent regarding the price, in the same way that a stock exchange ultimately does not care if a stock price goes up or down because they are catering to both buyers and sellers. He further specified that although speed is important (because it allows them to sell cars more quickly on a given day), he sees speed as primarily an input into whether a car sells or not. Specifically, he said, “Speed tends to sell and sell for a higher price. It puts adrenaline into the mix for the buyer.” Based on these conversations regarding what makes a “good” auctioneer for this particular company, our focus in the empirical section below is primarily on the probability-of-sale metric. However, we also provide results on price and speed.

3. Empirical analysis

3.1 Empirical strategy

One measure of auctioneer heterogeneity would be to simply calculate the average conversion rate, price of sale, and speed for each auctioneer in our dataset. Analyzing the variation in these averages across auctioneers could provide an indication for the degree to which an auctioneer can impact auction outcomes. Given the discussion of how auctioneers are allocated to lanes reported in the previous section, a concern with this approach is that these raw comparisons may result in performance dispersion that is due to omitted variables and not differential auctioneer ability. Therefore, our main analyses of auctioneer heterogeneity are based on the estimation of versions of the following regression model that allow us to control for various factors that may not be randomly assigned to auctioneers:

$$Y_{ik} = \alpha + \beta_k + X_i' \gamma + \varepsilon_{ik}. \quad (1)$$

Y_{ik} is one of our main outcome variables: an indicator for whether the car sold, the residual sales price, or time on the block (seconds). Individual cars are indexed by i and auctioneers by k . The vector X_i includes, depending on the specification, fixed effects for various characteristics of car i (sellers, auction day, lane number, etc.). The estimates of interest are the $\hat{\beta}_k$ s, the auctioneer effects.

Because the individual $\hat{\beta}$ s will depend on which auctioneer is excluded from the regression as the baseline, it is useful to have a normalization so that auctioneer effects are not sensitive to this specification issue. We thus compute:

¹² The recent discussion of the wholesale auto auction industry in Treece (2013) explains the importance of conversion rates to auction houses and also highlights the important role a good auctioneer can play in increasing conversion.

$$\hat{\beta}_{norm,k} = \hat{\beta}_k - \frac{1}{M} \sum_{j=2}^M \hat{\beta}_j \text{ for } k = 2, \dots, M; \quad (2)$$

$$\hat{\beta}_{norm,1} = 0 - \frac{1}{M} \sum_{j=2}^M \hat{\beta}_j,$$

where $k = 1$ denotes the omitted auctioneer in Equation (1).

Our interest is in understanding whether there is substantial heterogeneity in these normalized auctioneer effects. Statistically our question of interest is whether the β coefficients are jointly different from zero, which can be addressed through standard metrics such as F -tests. It is, however, also very useful to be able to talk about the economic magnitude of our findings by focusing on measures such as the spread between auctioneers with high effects versus those with low effects. A challenge here is that even if there is no meaningful underlying heterogeneity in auctioneer ability, we would still expect random sampling variation to generate some degree of dispersion between our estimates of the best auctioneer and the worst auctioneer. This would especially be an issue if our effects were being estimated off of a smaller sample size. We therefore also perform analyses using a Bayesian Shrinkage procedure which corrects for sampling variation and has been used in many other settings such as evaluating differences in teacher quality and organizational productivity.¹³ Specifically, we calculate:

$$\hat{\beta}_{norm-shrink,k} = \lambda_k \hat{\beta}_{norm,k} + (1 - \lambda_k) \frac{1}{M} \sum_{j=1}^M \hat{\beta}_{norm,j}, \quad (3)$$

with $\lambda_k = \frac{\theta}{\theta + \sigma_k^2}$, where θ is the variance of the 60 normalized estimates and σ_k^2 is the square of the estimated standard error of each $\hat{\beta}_{norm,k}$. Because the effects are normalized, note that $\sum_{j=1}^M \hat{\beta}_{norm,j} = 0$ by construction; thus the shrinkage estimator reduces to $\frac{\theta}{\theta + \sigma_k^2} \hat{\beta}_{norm,k}$ for each k .

3.2 Heterogeneity in auctioneer performance

We begin by estimating the model in Equation (1) using probability of sale as the outcome of interest. We estimate 8 different specifications, where each specification adds additional controls. The first specification includes no controls (just the auctioneer fixed effects). Once again, we are interested in the variation in auctioneer fixed effects. The first column in Table 2 provides the standard deviation of the auctioneer fixed effects for the various specifications using probability of sale as the outcome of interest. Specification 1 (raw values) suggests that the standard deviation in auctioneers' ability to sell cars is .051. Taken literally, this suggests that a one standard deviation improvement in auctioneer ability translates into a 5.1 percentage point higher probability of sale (off a base of 53%). The solid line in Figure 1 graphically presents these raw auctioneer effects by ranking the 60 auctioneers from worst to best and plotting their associated fixed effects. There is a remarkable amount of variation across auctioneers with

¹³ See, among others, Chandra, Finkelstein, Sacarny, and Syverson (2013); Jacob and Lefgren (2005); and Morris (1983).

the two highest-performing auctioneers being able to sell cars at more than a 10 percentage point higher rate than average.

The concern with these raw performance measures is that unobserved assignment of cars to auctioneers could be taking place. Based on discussions with the auction house, a primary confounder with the raw data is that certain auctioneers may be systematically assigned to sellers that have lower or higher reservation values than other sellers. To control for this concern, we include seller fixed effects in the second specification.¹⁴ Figure 1 illustrates how including these controls significantly reduces the amount of variation across auctioneers. Table 2 indicates that the standard deviation of auctioneer fixed effects is reduced from .051 to .038 when seller fixed effects are included. One question about including these controls is whether the auctioneer fixed effects are simply dampened, or if the ranking of the auctioneers is also significantly changed. The second column in Table 2 provides the coefficient of correlation between specification 2 (and the other specifications) and the previous specification and also t-stats in brackets. The correlation coefficient of .94 suggests that including seller fixed effects reduced the variation in auctioneer fixed effects, but did not greatly alter the rank order of the auctioneers.¹⁵

Likely due to macroeconomic factors, the probability of sale in our data changed substantially throughout the sample period. Once again, this can bias the dispersion of auctioneer fixed effects if some auctioneers worked more in certain periods during our sample than others. In Specification 3, we include time controls—both auction day (day*month*year) effects and time of day (hour-by-hour) effects. Figure 1 and Table 2 indicate that these controls reduce the amount of variation in the auctioneer fixed effects. Specification 4 includes fixed effects for the 55 lanes that operated at some point during our sample. This produces a slight decrease in the standard deviation of auctioneer fixed effects. We continue to find that the rank ordering of auctioneers is very similar from one specification to the next.

Specification 5 begins to include car characteristics in the model by adding car-make effects. Specification 6 includes age interacted with make (make*age) and also a 5th-order polynomial in the number of miles on the car's odometer. Specification 7 adds the car model into the interaction (make*model*age) as well as the miles polynomial. Specification 8 adds the body type of the car into the interaction (make*model*body*age) in addition to the miles polynomial. As can be seen in Figure 1 and in Table 2, moving from Specification 4 to Specification 8 neither impacts the standard deviation of the auctioneer effects, nor changes meaningfully the rank ordering of the estimates.

After including the controls mentioned above, we are left with an estimate suggesting that a one standard deviation improvement in auctioneer ability results in a 2.3 percentage point increase in the

¹⁴ We include a dummy variable for each of 1,087 sellers who sold at least 100 cars during our sample. The omitted category includes all sellers who sold less than 100 cars during our sample period.

¹⁵ The reported correlation coefficients are based on correlation of values (Pearson). Rank-correlation coefficients (Spearman) are very similar.

probability of selling a car (off a base of 53%). Panel B of Figure 1 provides 95% confidence intervals for each of the auctioneer fixed effects. One remaining question is how much of this variation we would expect due simply to sampling variation. To answer this question, we apply the Bayesian Shrinkage procedure discussed above to these estimates. The standard deviation that we find for Specification 8 after applying this procedure is: .0220 (compared to .0228 without the shrinkage procedure). Because of the large sample of auctions for each auctioneer in our data, sampling variation is small relative to the amount of variation in the estimated fixed effects.

We now turn to the other two performance metrics for auctioneers. The first is residual price, i.e. the price that was obtained by the auctioneer for a sold car minus the wholesale blue book value as calculated by the auction house using a proprietary formula. We “residualize” the price as a way to absorb additional unobserved heterogeneity that may exist about the car that is hard to control. The second performance metric is the amount of time that an auctioneer takes to run an auction (in seconds).

The results for these two metrics are presented in the second and third set of columns in Table 2. The standard deviation in raw values across auctioneers is very large (\$219) and is reduced to \$55.84 after including seller fixed effects. This suggests that some nonrandom sorting of cars to auctioneers is taking place in this environment. The standard deviation for the residual price effects stabilizes after Specification 4 at about \$40.¹⁶ The time-on-the-block effects are fairly stable, especially after controlling for seller fixed effects. The estimates imply that a one standard deviation increase in auctioneer speed is associated with running an auction in 6 fewer seconds (off a base of 103 seconds). The stability in these findings is an indication of speed being an individual characteristic or style which does not depend heavily on the car being auctioned off, the seller, or other environmental contingencies.

Sampling variation can explain 20-25% of the variation in the residual price effects. Specifically, the standard deviation for Specification 8 with Bayesian Shrinkage applied is \$31.99 (compared to \$41.78 without the shrinkage). The time effects are not very affected by sampling variation with a standard deviation of 5.87 once shrinkage is applied (compared to 6.07 without the shrinkage). Thus, with the exception of residual price (which was estimated to have a fairly small amount of variation in fixed effects to begin with), sampling variation appears to have very minor effects on our outcomes of interest.

3.3 Identifying auctioneer effects from shift changes

In this section, we propose a second approach to causally identify estimates of auctioneer ability that uses natural variation associated with work shift changes. We then compare these new auctioneer estimates with the estimates from the previous section.

¹⁶ It is not surprising that the residual price effects are not affected by car characteristics (make, model age) because these are almost surely being taken into consideration by the wholesale blue book value that the company creates.

On a typical auction date, two auctioneers will be assigned to work on each lane. These two auctioneers will take turns auctioning off cars in that lane. Auctioneers may switch at any time, but we observe that auctioneers typically switch roughly every 30 or 60 minutes in what appear to be somewhat regular shift-length norms. In particular, we see very few instances of an auctioneer who is on the block for much longer than 60 minutes at a time (Appendix Figure A.1).

We can exploit the variation in auctioneers that occurs within a lane on a given day by including lane*day fixed effects when estimating auctioneer ability.¹⁷ By looking within a lane on a given day, we are able to control for additional unobserved factors that may exist (number of buyers at the auction located near a given lane, unobserved characteristics about the cars/sellers assigned to that lane, etc.) when estimating auctioneer fixed effects.

We estimate the model in Equation (1) while controlling for seller, time of day, and 13,687 lane*day fixed effects. Figure 2 provides scatter plots of the estimates from Specification 8 in the previous section and the estimates using the specification described here for each of our three performance metrics. The estimates that we find are strongly correlated across identification strategies: the t-stats for probability of sale, residual price, and time on the block are 18.9, 6.51, and 15.46 respectively. Finding similar estimates when looking within a lane*day lends credibility to the estimates found in the previous section.

3.4 Stability of heterogeneity over time

If these estimated effects reflect persistent differences in auctioneer abilities, then we would expect them to be fairly stable over time. In particular, an auctioneer who performed better in the first half of our sample (2007-2009) should also perform better in the second half of our sample (2010-2013). In Figure 3 we plot the fixed effects for the 49 auctioneers who were full time employees in both the first and second half of our sample period. We find a strong, positive correlation with probability of sale (t-stat = 4.91) and time fixed effects (t-stat = 7.32) between the two sample periods. We do not find persistence in the residual price fixed effects across the two periods (t-stat = -0.10). This is consistent with our other findings which suggest that the price effects we estimate are not as strong or well-identified as the effects on probability of sale and speed. The persistence of the probability of sale and speed effects, however, suggests that we are detecting features of the auctioneers that are stable and robust across time.

3.5 Correlation between performance measures

¹⁷ One might be tempted to use a regression discontinuity design based on shift changes. However, because changes can occur endogenously (perhaps an auctioneer feels like he/she underperformed on the last couple of auctions and then decides to switch) and because switches likely occur at the same time as the cars being sold switch from one seller to the next, we are hesitant to try to identify off of discontinuous work shift changes.

As discussed earlier, the primary objective of auctioneers as seen by the auction house is to maximize the probability of selling a car. However, it is informative to consider how auctioneers who excel in selling a large fraction of their cars perform in the other two metrics (residual price and speed).¹⁸ It is possible that the individual auctioneers who have the best performance for the probability of sale achieve this at the cost of one of the other metrics. For example, perhaps it is auctioneers who go really slow and take a lot of time to do the auction that are able to achieve better conversion rates. Conversely, a finding of a positive correlation between conversion rates, prices, and speed would be further evidence of the existence of an “auctioneer ability” heterogenous in the relevant population.

A concern with correlating the time-on-the-block effects with other outcomes is that there may be a mechanical bias. The average time on the block for cars that sell is approximately 11 seconds longer than the time on the block when the car does not sell. This may be in part due to the extra recording time that is required when a sale occurs. Thus, if an auctioneer is able to obtain a higher probability of sale than another auctioneer, he/she may mechanically have a longer time on the block as well. In order to avoid this bias, we produce and use time on the block fixed effects for each auctioneer based only on cars that sold rather than all cars. Thus, we are able to obtain a measure of how fast an auctioneer typically performs auctions that is uncorrelated with the conversion rate of the auctioneer. Appendix Figure 2 illustrates that the time-on-the-block fixed effects using sold cars only are highly correlated with the time-on-the-block fixed effects when using all auctions (t-stat = 22.00). An auctioneer’s fixed effects for time-on-block for sold cars also correlates strongly with his fixed effect for time-on-block for unsold cars (Figure A.2 Panel B). This suggests that time-on-block likely reflects systematic differences across auctioneers in the speed with which they conduct their auctions, regardless of the auction outcome. From this point on we will always use the time-on-the-block fixed effects from sold cars in order to avoid bias when doing correlations.

Using Specification 8 from Section 3.2, Panel A of Figure 4 shows the correlation between probability-of-sale fixed effects and residual-price fixed effects, Panel B shows the correlation between probability-of-sale fixed effects and speed, and Panel C shows the correlation between residual-price fixed effects and speed. Auctioneers with the highest fixed effects for probability of sale also have higher than average fixed effects for prices obtained (t-stat = 3.29) and are marginally faster at selling cars as well (t-stat = -1.62).¹⁹ We also find that auctioneers who achieve high prices for cars are faster than

¹⁸ Correlating these measures provide insight into the possible mechanisms that the best auctioneers may be using and will be discussed in further detail in Section 4.

¹⁹ A larger time-on-the-block fixed effect represents an auctioneer who takes more seconds to sell a car on average. Thus, a negative sign on the correlation between time-on-the-block and probability of sale suggests that auctioneers who sell more cars are faster than average.

average (t-stat = -2.52).²⁰ Although the statistical power to identify these correlations is somewhat limited, we find no evidence that auctioneers who are doing well on their main objective function (maximizing probability of sale) are doing so at a cost to secondary objectives. If anything, we find that auctioneers who are better in one dimension are better in the other dimensions as well. This supports the statement made by the auction house's general manager that "sales price and speed are generally the parents of conversion rate" and is something to which we will also refer when discussing potential mechanisms for these effects in the next section.

3.6 Comparing the estimates with subjective measures of auctioneer performance

As another check on the validity of the estimated auctioneer effects, we compare our "objective" estimates of auctioneer ability with "subjective" evaluations of auctioneer ability produced internally by the auction company. At our request, the auction company produced evaluations for the 41 full-time auctioneers working in the Fall of 2012 (prior to them seeing any auctioneer-specific results generated by us). The evaluations they produced were based on a multidimensional subjective assessment by a panel of three senior auctioneers. This panel considered a range of inputs of their own choosing in order to produce a summary metric in 0.1 increments which we place on a scale from 0 (worst) to 1 (best).²¹ In Figure 5 we correlate the company's subjective rankings with our estimated fixed effects (once again using the full model as from Specification 8 in Table 2). Panels A, B, and C provide correlations between the subjective evaluations and fixed effects for probability of sale, residual price, and speed respectively. We find significant correlations between their measure of who the best auctioneers are and our measure of auctioneers who have a high probability of sale (t-stat = 4.62), who obtain high prices (t-stat = 2.09), and who conduct fast auctions (t-stat = -2.03). The correlations we find, especially with the probability-of-sale metric, are remarkably strong and lend additional credibility to the idea that we are identifying true differences in auctioneer ability.

3.7 Predicting job termination decisions

Due to the recession that took place during our sample period, the company significantly downsized the number of full-time auctioneers between the start and end of our sample. Specifically, there are 59 full-time auctioneers at the start of our sample. Of these 59 auctioneers, 18 were no longer working for the company by 2013 (and one new auctioneer was hired). This downsizing provides us with an additional test for the validity and relevance of our measure of heterogeneity in auctioneer ability. We are interested

²⁰ Simple exploratory factor analyses are consistent with the presence of a "common factor" underlying the auctioneer fixed effects on conversion rate, residual price, and time on the block.

²¹ The original scale elaborated by the company is from 2 (worst) to 1 (best).

in analyzing whether the auctioneers who stayed in the sample (“stayers”) were better than the auctioneers let go during the downsizing who exited the sample (“goers”).²²

Figure 6 displays the auctioneer effects from the fully specified model (Specification 8) for each performance measure. The auctioneers who left the company before 2012 are highlighted in red. Note that many of the worst-performing auctioneers in each dimension (the left tail of auctioneers in panels A and B and the right tail of auctioneers in panel C) left the firm during the downsizing. In contrast, the large majority of the best-performing auctioneers (the right tail in panels A and B and the left tail in panel C) were retained by the firm. Regressions of the auctioneer fixed effects (from Specification 8 above) on a dummy for whether the auctioneer was a stayer or not imply that stayers are, on average, more likely to sell a car by 1.5 percentage points (t-stat = 2.53), have residual prices that are \$25 higher (t-stat = 2.09), and take 6.7 fewer seconds when selling a car (t-stat = -3.36). Again, the fact that our ability measures significantly predict who exited the sample during a downturn provides evidence in favor of our metric representing true ability.

3.8 Benchmarking the impact of auctioneer ability and the impact on expected revenues

Having established that heterogeneities exist among auctioneers, we now provide simple calculations, based on the point estimates from the analyses above, to compute the impact of these estimates on some relevant economic variables. On average, each full-time auctioneer performs approximately 2,000 car auctions per year of our sample. An auctioneer who moves from the 10th percentile to the 90th percentile in our probability-of-sale metric (a 5.6 percentage point increase in probability of sale off a base of 53%) will sell approximately 123 more cars each year. Assuming an average fee to the auction house of \$200 for each car sold, this translates to an increase in revenue for the auction company of \$24,600.²³

Similar calculations can be done for the value of auctioneers who systematically obtain higher prices and/or go faster. In particular, the average difference in residual prices obtained by the 90th-percentile auctioneer and the 10th-percentile auctioneer is about \$96, and the difference in time on the block is 12.6 seconds (14.7 seconds for sold cars). However, it is harder to translate these values into company profit since fees received are not based directly on these measures.

Another way to benchmark the results is to compare our estimated effects with the impact of changes in other relevant variables in our data, as well as with results from related studies that estimate the effects

²² Unfortunately, we do not have hard data on whether the auctioneers that left the sample were fired or left voluntarily. Our discussion with the auction company suggests that the majority if not all of these auctioneers left involuntarily. To the extent that a few of the auctioneers left on their own accord, this would bias us against finding significant differences between stayers vs. goers.

²³ These calculations are rough and ignore many other potentially important factors. For example, if the probability of sale increases, it could cause more sellers to bring their cars to this market suggesting that the value of the auctioneer is even higher. It is also possible that an auctioneer that is able to sell more cars is causing lower sales for the other auctioneers.

of certain changes in auction design and information structure on similar outcomes. Within our data, we estimate the 90th-10th percentile difference in residual prices to correspond to the effect of a difference of 1,136 miles between two otherwise identical cars.²⁴

As for related studies, Tadelis and Zettelmeyer (2011) estimate the impact of randomly providing additional information about car quality from a reputable source in a wholesale car auction. They find that additional information translates into a 6.3 percentage point increase in probability of sale and a \$236 increase in average price. These effects are slightly bigger than those we estimate to be the difference in average probability of sale and price obtained by an auctioneer at the 10th and at the 90th percentile. Coey, Larsen and Sweeney (2013), using similar wholesale car auction data, find that excluding a last-minute, high-value bidder, which can occur due to computer lag, results in a 6.6% decrease in the probability of sale, again slightly larger than but similar in size to the effects we find. Similar impacts have been found from changes in relevant economic and financial conditions at a more aggregate level; Hortaçsu, Matvos, Syverson, and Venkataraman (2013) show that a 1000-point increase in the CDS spread for an auto manufacturer is associated with a drop in average prices for that manufacturer's used cars at auctions of \$68.

An important theoretical benchmark from the auction design literature to which our results can be compared comes from Bulow and Klemperer (1996), who demonstrate that the participation of one additional random bidder increases seller revenue more than an optimal reserve price would. Coey, Larsen, and Sweeney (2013) present a method for calculating the effect of adding a random bidder on final prices and find that this effect is at most \$160.²⁵ This implies that the effect we find of moving from the 10th percentile to the 90th percentile auctioneer captures a substantial portion of the effect of increasing competition at auctions, and, in turn, a substantial portion of the effect on seller revenue which would come from designing the auction optimally.

4. Exploring the sources and mechanisms of auctioneer heterogeneity

The analyses in the previous section provide robust evidence that, even in a well-functioning auction market, individual auctioneers can significantly impact key market outcomes. This suggests that auctioneer skills are a real phenomenon. Although the primary contribution of the paper comes from documenting the systematic variance in outcomes across auctioneers, a natural next step is to explore the

²⁴ This estimate was obtained by running a regression of residual price on the same right-hand side variables as in Specification 8, but with miles entered linearly. The estimated coefficient on miles is -.00845.

²⁵ As demonstrated in Coey, Larsen and Sweeney (2013), the Bulow and Klemperer (1996) effect of adding one more random bidder to an N -bidder auction is given by scaling the average gap between the second and third-highest bids from $N+1$ -bidder auctions by a factor of $2/(N+1)$. Note that the \$160 estimate comes from auction sales which were primarily fleet/lease cars; the estimate could differ at dealer auctions.

mechanisms that might determine relative auction success. Uncovering these mechanisms is an interesting avenue for a whole body of future research and will likely be best addressed using experimental techniques. However, in this section we begin to explore these potential mechanisms, noting that the nature of the available data here do not allow us to reach any fully conclusive claim about mechanisms. We begin with a short discussion of some potential sources of heterogeneity. We then present qualitative evidence from a survey prepared for this paper in which professional auctioneers were asked to comment on and rank various tools and characteristics that define an effective auctioneer. Finally, we provide and discuss quantitative evidence from our data (some of which was already presented in Section 3 above) that helps establish the potential relevance of the various mechanisms considered here.

4.1 Potential mechanisms

We consider five broad mechanisms that could drive heterogeneity in auctioneer ability:

- 1. Direct information revelation.** One way in which auctioneers could potentially affect market outcomes is by directly revealing information about the products being sold. In particular, the linkage principle (Milgrom and Weber, 1982; Milgrom, 2004) would predict that an auctioneer who could better commit to revealing truthful information about the cars being sold could expect to generate higher prices. However, it is important to note here that the predictions of information revelation require that the auctioneer have private information about the value of the good being sold, which as we discuss below is very unlikely in this market.
- 2. Persuading sellers to lower reservation values.** The main effects documented in this paper concern the ability of an auctioneer to achieve a sale. One of the obvious ways in which auctioneers could differ in their ability to achieve a sale would be if they differ in an ability to persuade sellers to lower their reservation values to match the available market price. If some auctioneers have more credibility with sellers, they may be better at convincing sellers to lower reservation values and accept the outcome of the auction.
- 3. Generating patterns of bids that increase revelation of bidder values.** In Milgrom and Weber's (1982) model of English auctions with affiliated values, bidders reveal something about their valuation as they are observed dropping out of the bidding, and it is this extra information that leads to predictions of higher revenues from English auctions relative to other formats. As a number of papers have highlighted, however, in real-world English auctions of the type we observe here, many potential bidders remain silent during the auction and never reveal information about their valuation (Haile and Tamer, 2003; Harstad and Rothkopf, 2000). Thus real-world English auctions may not achieve the same revenue-enhancing benefits that one would predict from classic theory. If some

auctioneers are particularly good, however, at getting those with lower private signals about the market value of the car to initially bid, they could increase the information revealed and hence raise overall prices. For example, some auctioneers may be particularly good at choosing the starting prices or bid increments that they call in a way that induces a greater number of initial bids from those with low valuations. Or, perhaps some auctioneers are better at identifying low-valuation bidders and recognizing their bids early before focusing on the bids by those who will eventually win the auction.²⁶

- 4. Reducing search frictions.** Much of the activity at wholesale auto auctions occurs across a range of auction lanes simultaneously. Bidders may face search costs and cognitive limits that affect their ability to process information and pay attention to the available cars up for auction. Auctioneers may then differ in their ability to help bidders “match” to cars through techniques that increase the salience of cars for bidders who are likely to value them. For example, Steve Lang, a former award-winning auctioneer who is now a buyer and seller at auto auctions and owner of a popular car blog, stated, “I’ll go to my strongest buyers first. Always” (2009b), and B. J. Lewis, another award-winning auctioneer, declared, “Knowing the buyer is really important...You’re not watching 20 people all at once. For example, you might know that [a dealer] buys a certain kind of car” (Reynolds, 2003).
- 5. Exploiting behavioral biases.** A final source of heterogeneity may come from variation in the ability that auctioneers have to exploit potential behavioral biases in auction settings. Auction environments are exciting and emotions may sway bidders. It could be that some auctioneers are better at generating the sort of excitement that induces “irrational exuberance” and “auction fever” (Ku, Malhorta, and Murnighan, 2005; Ockenfels, Reiley, and Sadrieh, 2007; Malmendier and Szeidl, 2008; Podwol and Schneider, 2011). Describing his experience, Steve Lang stated, “[I] may have only been 26. But when I was on the block or in the lane, I had the manipulative mind of a 62-year-old charmer and my job was to use my powers of persuasion to create the urgency to buy. An inflection of voice. The right word. The right implicit use of eye contact, hand or body gesture...” (Lang, 2010). Another possibility is that good auctioneers may be particularly skilled at “anchoring” bidders to certain reference points (e.g. prices) through the choice of the opening price, referred to as the fish price. At wholesale car auctions, the auctioneer starts by calling out a high bid, then lowers the price until a bidder indicates a willingness to pay at that price, at which point the ascending auction begins. Of this practice, Genesove (1995) commented, “The auctioneer’s initial price almost always exceeds the winning bid. What effect it has on the subsequent bidding is an open question. One auction official,

²⁶ Identifying buyers at auctions can be particularly challenging given what one writer called the “barely discernible sign language used by the buyers” (Reynolds, 2003). Lang (2009a) similarly argued that hand signals used by bidders at auto auctions would be confusing to a lay observer.

otherwise quite forthcoming about the workings of the auction, avoided discussion of the initial price, aside from describing its choice as an important part of the auctioneer's art.”

There are a number of reasons why it is generally challenging to disentangle the importance of these potential mechanisms from observational data. For one thing, these forces do not have to be mutually exclusive in any way. For example, it could be that an auctioneer who is able to generate excitement (Mechanism 5) gets more initial low bids that reveal information (Mechanism 3) to higher-value bidders. An auctioneer who generates excitement might also draw attention to the cars on his lane and get better matches (Mechanism 4) and exciting auctions with many bidders may give sellers more confidence to accept the auction price, which would look observationally a lot like Mechanism 2. Another challenge is that many of the behaviors that successful auctioneers might employ could be related to different mechanisms. For example, patterns of starting prices (“fish prices”) could be used to successfully induce low-value bids (Mechanism 3) or to induce anchoring (Mechanism 5), so that simply observing heterogeneity in patterns of fish prices across auctioneers will not be enough information to identify a mechanism.

Despite the challenges inherent in identifying these mechanisms in a field context, we believe that it is possible to provide a range of evidence, from both surveys and data analysis, which begins to speak to the potential relevance of these different sources of heterogeneous ability. In the next two sub-sections we present evidence from a survey of auctioneers and then discuss observable patterns in our data that shed light on the mechanisms at play.

4.2 Survey evidence

Our first approach in trying to understand the mechanisms better is through an anonymous survey that the auction house conducted with 33 of their auctioneers. The questions included on the survey were based on preliminary discussions with the auction house and after some limited data analysis for this project. As such, the survey is not particularly scientific, but we believe it nonetheless provides a useful starting point for considerations of the mechanisms used by auctioneers to achieve success. The auctioneers were asked to rank the importance of a number of skills/topics in determining a particularly effective auctioneer on a scale from 0 (very unimportant) to 5 (very important). These rankings are reported in Figure 7. They were also asked to choose one statement among four options which best describes the most important role of an auctioneer when auctioning off dealer cars in the wholesale market. The resulting answers to that question are presented in Table 3. Finally, the survey included an open response box that asked auctioneers to think of auctioneers they found “especially effective” and to describe what made those auctioneers different from an average auctioneer.

The clearest fact that emerges from these surveys, discussions with the auction house, and our own observations of the auction process is that auctioneer performance differences are not driven by an ability to convey relevant information about the cars being auctioned. As Table 3 shows, of the 33 auctioneers, only one thought that the most important role of auctioneers in this setting was to provide expert information about cars. The options “Providing information about cars not otherwise available to bidders” and “Highlighting positive features of the car” also received low rankings reported in Figure 7. The institutional structure of these auctions also makes the information-revelation mechanism highly unlikely. Auctioneers rarely, if ever, discuss the features of a car during the one to two minutes while the car is on the auction block. The bidders in these auctions are experienced used-car dealers who know a great deal about the retail market for the cars being sold. The auctioneers do not inspect the cars they auction and see them for the first time a few seconds before beginning the auction. Bidders, in contrast, can walk around the car, inspect it prior to the auction, and are physically closer to the car during the auction than the auctioneer. Thus, although theoretically relevant and empirically applicable to other contexts, direct information revelation is highly unlikely to be an important source of auctioneer heterogeneity in this setting.

The survey evidence also provides little support for the possibility that good auctioneers are more successful at persuading sellers to accept fair prices. Again only 1 of 33 auctioneers (Table 3) chose that option as the most important factor in determining auctioneer success. That mechanism also received relatively low rankings on the 5-point scale (Figure 7).

The other three mechanisms (3 – 5) are difficult to disentangle via a simple survey, as they all involve effects on buyer behavior. In Table 3 we see that auctioneers overwhelmingly (31/33) selected the option that “auctioneers create a sense of excitement, competition, and urgency among buyers that encourages more bidding” as the most important role of the auctioneer. That is consistent with the possibility that Mechanism 5 is important, but because there were no options in that part of the survey that addressed the other buyer-related mechanisms, it does not preclude the importance of mechanisms 3 or 4. Of the options for important skills/tactics included in the survey, those receiving the highest ranking (Figure 7) were “creating competitiveness between bidders,” “spotting interested but reluctant bidders,” “having an effective chant,” and “increasing engagement and excitement by running a fast-paced auction.” Most of these seem primarily consistent with mechanisms related to behavioral biases, though spotting interested but reluctant bidders could reasonably be related to either Mechanism 3 or Mechanism 4. Interestingly, calling out good starting prices, which might plausibly be a way to generate bids from those with low valuations (Mechanism 3) received low rankings.

In their open-ended comments to questions asking to describe what separates an effective auctioneer from an average auctioneer, several respondents highlight the importance of speed and creating a sense of

urgency among bidders through means that appear to target “behavioral factors.” For example, one auctioneer stated, “The most effective auctioneer's [sic] that I have seen tend to use speed as tool which create's [sic] a sense of urgency in bidders, force's [sic] split second decisions and does not allow for bidders to doubt or second guess their bidding decisions.” Another auctioneer stated that a good auctioneer “knows when to slow down and give someone that extra second to think to make the sale or for some people speed up so they get caught up in the bidding and end up paying to [sic] much.”

4.3 Quantitative evidence on potential mechanisms

In this subsection we consider patterns in our data that potentially speak to the relevant sources of heterogeneity. We begin by recalling some of the findings reported in Section 3 (above) that offer relevant insights on mechanisms and then turn to additional data analysis.

The patterns of correlations between auctioneer effects in conversion rates and prices can shed light on the relevance of Mechanism 2 (persuading sellers to lower reservation values). If auctioneers differed primarily in their ability to encourage sellers to lower their reservation values, then auctioneers with high conversion rates should find their average sales price to be lower conditional on sale. As seen in panel A of Figure 4, however, conversion rates and prices are positively correlated. This finding is consistent with the survey evidence and suggests that it is unlikely that the primary mechanism consists of auctioneers convincing sellers to lower their reserve prices.

The patterns related to the speed of auctions in Section 3 also help to speak to the relative importance of mechanisms 3 and 5. The finding that faster auctioneers tend to perform better, as shown in Table 3 and in panels B and C of Figure 4, serves as suggestive evidence in favor of an excitement-creation story and against the idea that good auctioneers aid in revealing information from low-valuation buyers. If auctioneers achieve success by generating more bidding from low-valuation bidders, one would expect the process to take a little more time than auctions where the auctioneer elicits bids closer to the final price from the outset.²⁷ In contrast, we observe that auctioneers who achieve better conversion rates tend to run faster auctions. Our discussions with auctioneers and the auction house, as well as the survey evidence, highlighted that the auctioneers believe that fast-paced auctions help to create a sense of

²⁷ Under the hypothesis that good auctioneers reveal more information about the bids of other participants, one might also expect the total number of bids received by the auctioneer to be higher for good auctioneers. We tested this hypothesis using data on the 16 auctioneers from the secondary dataset used below in analyzing fish price effects. We found a positive but insignificant relationship between auctioneer effects for conversion and auctioneer effects for total bids received. An additional mechanism which one would expect to manifest itself in good auctioneers taking longer and receiving more bids (unlike what we see in our estimates) would be that in cases where only one bidder is left and yet the price has not reached a level at which the seller would accept, some auctioneers may be better than others at signaling to the final bidder that he must continue to bid higher. This is referred to as “taking bids off the wall,” “taking bids from the vending machine,” or “taking phantom bids” (see Ashenfelter, 1989; and Vincent, 1995).

excitement in bidders.²⁸ Our findings on speed appear consistent with other work that has shown that time pressure induced by looming auction end-times appears to increase the propensity for overbidding (Ku, Malhorta, and Murnighan 2005 and Malhorta, 2010).²⁹

We also search for evidence as to whether some auctioneers are better at attracting certain types of bidders, aiding in the process of matching buyers to cars. To examine this hypothesis, we calculate three measures for each buyer: 1) size, given by the total number of cars purchased by the buyer in our full sample; 2) propensity to pay above market value, given by the average residual price paid by the buyer; and 3) match propensity, given by the percent of the buyer's purchases which were of a given make.³⁰ We then estimate the fully specified version of Equation (1) using these measures as outcomes. If auctioneers differ in their propensity to recognize the types of cars buyers are looking for, that effect might be especially relevant for buyers who buy large numbers of cars. The t-stat from a regression of auctioneer fixed effects for the probability of sale on auctioneer fixed effects for buyer size is 1.71, suggesting that good auctioneers may be marginally better at attracting high-volume buyers.³¹ Similar regressions of auctioneer sold fixed effects on propensity to pay over market value or buyer match propensity do not yield significant t-stats (0.41 and -0.93, respectively). Overall, we do not find strong evidence of the auctioneer differences in ability to sell cars being explained by differential ability to match buyers to cars.

We investigate anchoring effects by exploring whether auctioneers may generate anchors for the bidder through the "fish price," i.e. the initial price that they call. Our auction data do not include information on the fish price. However, we obtain partial information on initially called price from a secondary data source which contains cars sold by 16 different auctioneers.³² In this sample, we estimate auctioneer fixed effects for the probability of sale as well as for the residual fish price (fish price less the

²⁸ An alternative explanation for why speed would be positively correlated with auctioneer price effects and probability-of-sale effects would be that buyers with time costs may prefer to remain in the lane of a fast auctioneer, meaning that a fast auctioneer may lead to more bidders being present, which can in turn increase prices and conversion. Note, however, that this could imply that bidders have high costs of moving between lanes.

²⁹ Haruvy and Leszczyc (2010) and Lucking-Reiley, Bryan, Prasad, and Reeves (2007) find that on eBay, where auction duration is between one and seven days, longer-lasting auctions generate more bidder participation. However, Einav, Kuchler, Levin, and Sundaresan (2013) exploit experimentation at the seller level to find that auction duration does not affect auction outcomes on eBay. Our results, on the other hand, suggest that in the short-lived sales we examine, where the average auction duration is less than two minutes, speed can be an important factor.

³⁰ We use this measure as an outcome in equation (1) as follows: if the make of car i is Honda, and the winner of the car is buyer j , we replace Y_{ik} with the percent of all cars purchased by buyer j which were Hondas.

³¹ This marginal significance disappears, however, if instead of the actual volume of cars purchased we rank buyers according to their volume purchased and replace the outcome in equation (1) with the relative ranking of buyers. In this case, the t-stat drops to -0.12.

³² This secondary dataset is much smaller than our main dataset, containing information on dealer cars sold by 29 different auctioneers at three different auction house locations from January 2007 to March 2010. Sixteen of these auctioneers also sold cars through simulcast auctions, where the fish price is recorded (simulcast auctions are sales in which bidders could participate remotely online, although the actual auction still took place physically at the auction house and most bidders were physically present). Given that sellers at simulcast auctions are mostly fleet/lease sellers, we estimate sold effects from the dealers sample and use the simulcast sample only for estimating fish price effects. We follow similar sample restrictions as in our main dataset but restrict to auctioneers selling more than 100 cars due to the smaller sample size. This leaves us with a dataset of 68,924 cars in the dealers sample and 49,069 cars in the simulcast sample.

market value). Although we do find some heterogeneity (albeit noisy) among auctioneers in the (residual) fish price that they call for otherwise identical cars, these differences do not appear to translate to heterogeneity in conversion rates: The t-stat of a regression of auctioneer probability-of-sale effects on auctioneer effects for fish price (both from the fully specified model) is -0.68.

Taking all of this evidence together, and combining it with the evidence from our surveys and observations of auctioneers, a few patterns begin to emerge. First, auctioneer effects are not driven by an ability to reveal information about cars and also are likely not primarily a result of convincing sellers to change their patterns of reservation prices. We do not have conclusive evidence on the different mechanisms related to changing patterns of bids. The patterns that emerge most clearly, however, point to some role for auctioneers influencing bidder behavior through tactics that create excitement among bidders. Further, in terms of specific mechanisms, both auctioneer surveys and patterns in the data suggest that the use of speed and time pressure may be an important component of how auctioneers affect bidders' feelings of excitement and urgency during auctions.

5. Discussion and conclusion

The evidence presented in this paper shows that in well-functioning, high-stakes auctions, the specific manner in which the auction is run can have an important impact on the outcome. Using a large dataset from the wholesale used-car market, we find that auctioneers differ systematically in their ability to sell cars, as well as in the prices they get and the speed in which they do it; these differences are economically relevant.

Our results of a significant role of the auction process, and in particular of the “human” component in auctions, speak to the role that computerized online auctions may have in coordinating economic activity. There would seem to be strong efficiencies to computerized auctions, as they avoid the costs of employing professional auctioneers and auction-house staff and in online formats can avoid the often substantial transaction costs of bringing bidders and goods together in the same place. Yet recent work has documented that the popularity of online auctions may be fading (Einav, Farronato, Levin, and Sundaresan, 2012). Our findings suggest that human auctioneers have tactics that may improve the efficiency of auctions and, as such, might help to explain why computerized online auctions do not yet dominate the marketplace. Further studies into the behaviors of human auctioneers could provide important insights that can be used to improve the performance of computerized auction mechanisms and more generally may be useful for quantifying the potential efficiency losses from conducting naïve computerized auction processes.

Additional work is also needed to tightly pin down the mechanisms through which auctioneers affect outcomes, or the sources of auctioneer abilities. The evidence presented here is consistent with the

primary sources of these heterogeneities being due to non-information-based (or behavioral) factors, in particular those creating urgency among bidders. We hope that future research including controlled laboratory experiments can help shed light on the exact mechanisms involved.

Figure 1 - Auctioneer Differences in Probability of Sale

Panel A plots the normalized fixed effects for each of the 60 auctioneers in our data. The fixed effects are obtained from a regression model with no controls, and then adding seller fixed effects, auction day and time of day, lane fixed effects, and car type fixed effects (see Equation (1) above), and normalized following the procedure described in Equation (2). Panel B plots the fully specified model's fixed effects (Specification 8 in Table 2) along with 95% confidence intervals.

A: Comparison between specifications

B: Fully specified estimates with confidence intervals

Figure 2 – Comparison between Identification Strategies. The panels below provide scatterplots that show the correlation in fixed effects for auctioneers based on probability of sale (Panel A), residual price (Panel B), and time on the block (Panel C) between our two different identification strategies: the analysis within seller, auction day and time of day, lane, and car types fixed effects (Specification 8 in Table 2), and the identification based on shifts within a lane (lane*day) (Specification 9). Fitted lines are reported as well as the t-statistics from univariate linear regressions between the auctioneer effect estimates from the two identification approaches.

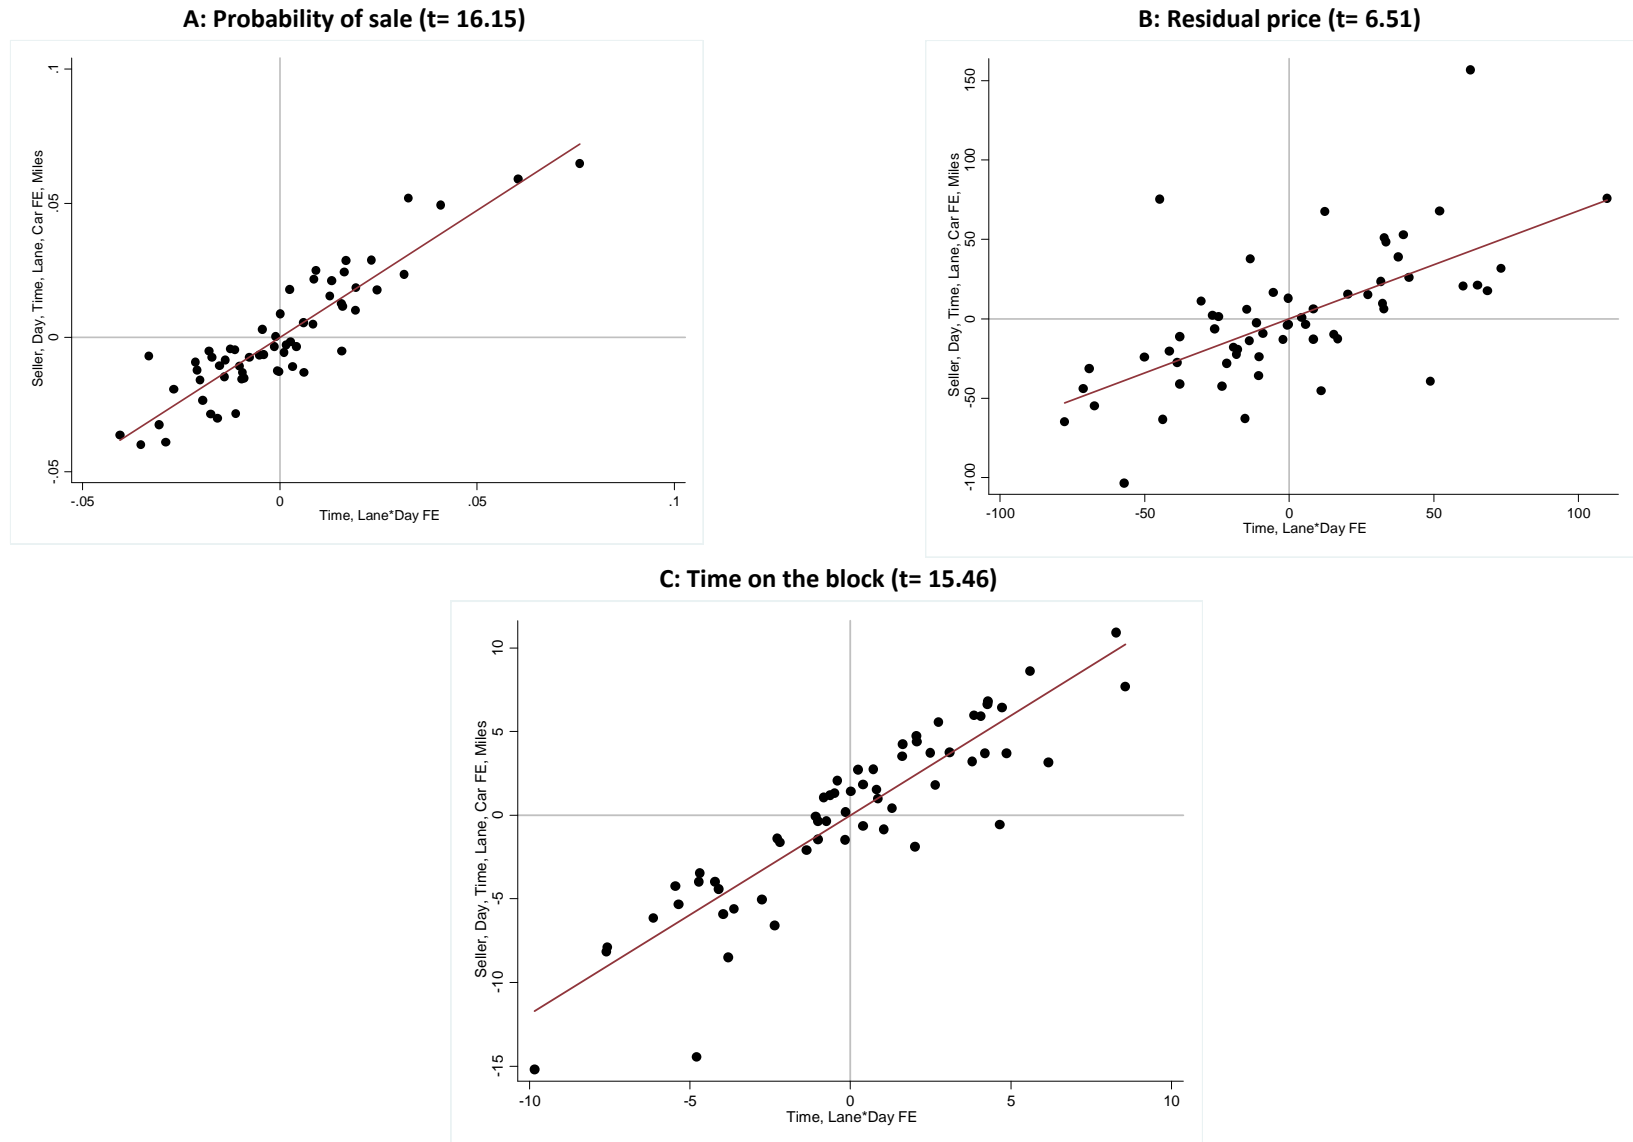

Figure 3 - Correlation of Fixed Effects between 2007-09 and 2010-13. Using the identification within seller, auction day and time of day, lane, and car types, we estimated auctioneer fixed effects separately using data for 2007-09 and then 2010-13. The panels below provide scatterplots that show the correlation in fixed effects between 2007-09 and 2010-13 for probability of sale (Panel A), residual price of sale (Panel B), and time on the block for sold cars (Panel C). Fitted lines are reported as well as the t-statistics from univariate linear regressions between the outcomes in the two years for each measure. The analysis here is limited to the 49 auctioneers with at least 2,000 observations in each of the two time periods.

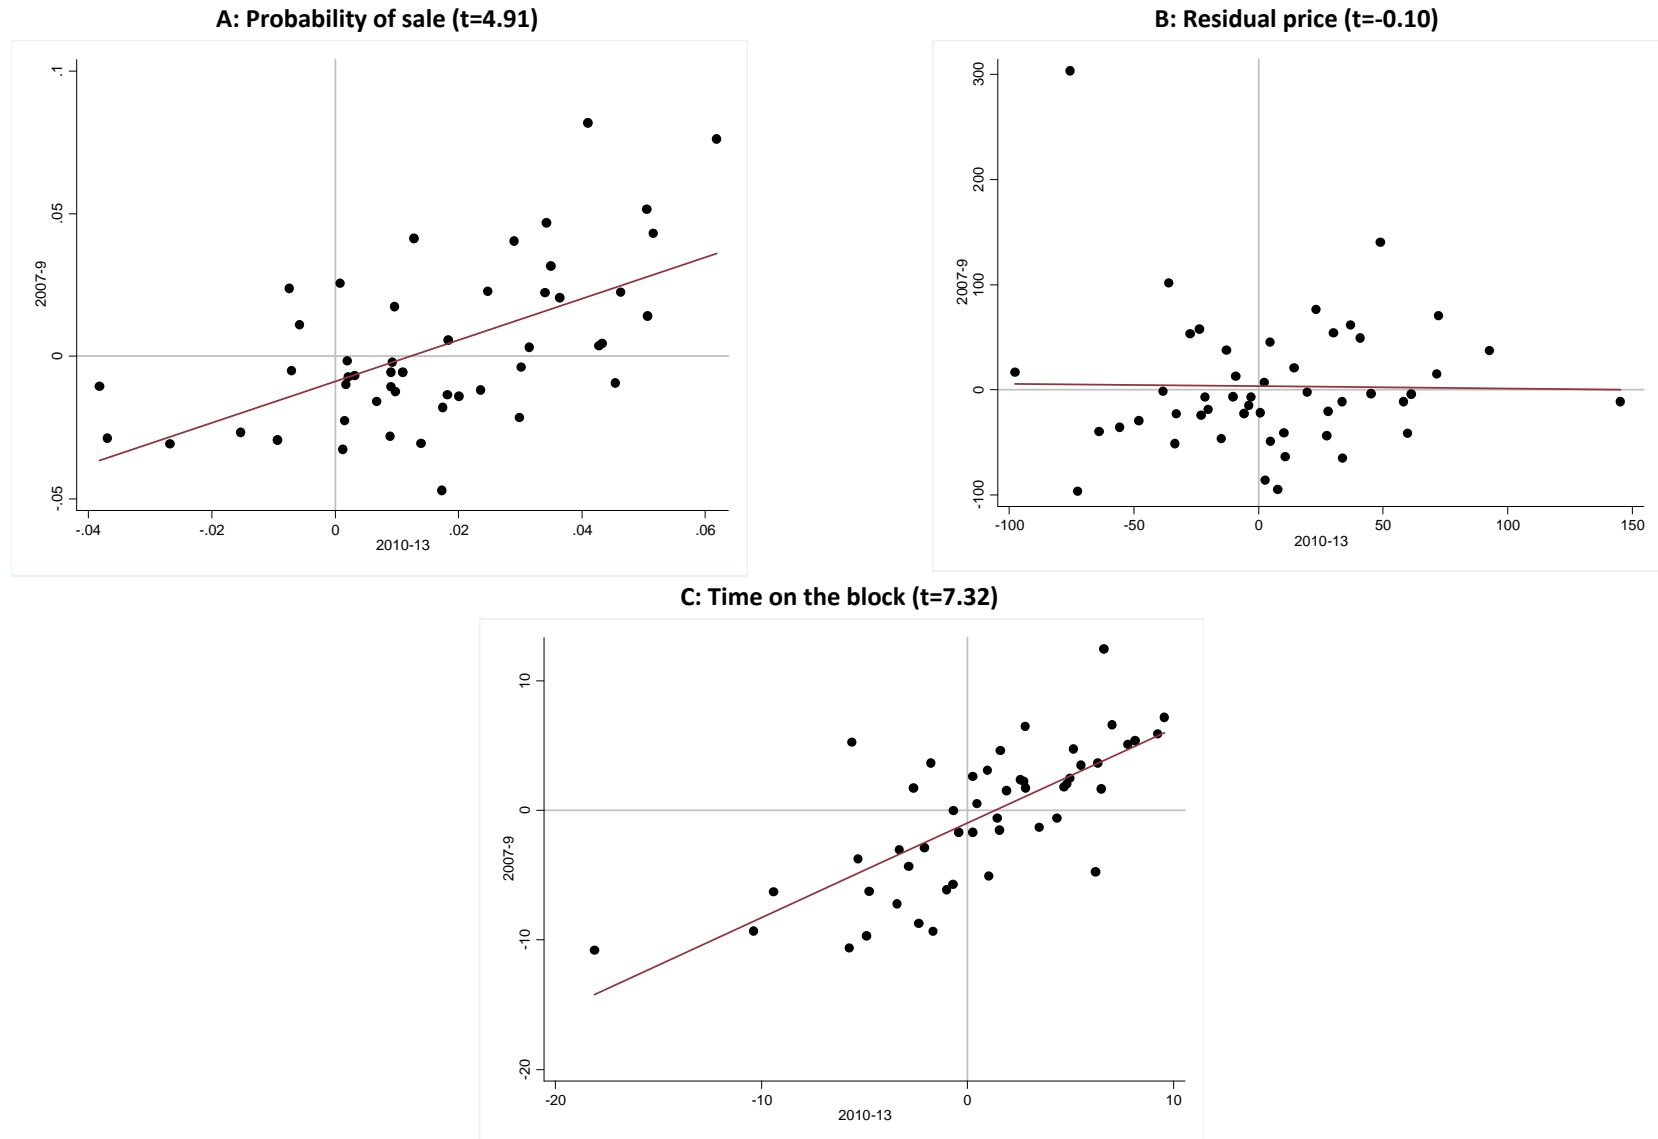

Figure 4 - Correlation between Performance Measures. The panels below provide scatterplots that show the correlation in fixed effects for auctioneers based on probability of sale, residual price, and time on the block for sold cars. All fixed effects come from the fully specified model estimates within seller, auction day and time of day, lane, and car types. Fitted lines are reported as well as the t-statistic from univariate regressions between the outcomes for each measure.

A: Probability of sale and residual price (t=3.29)

B: Probability of sale and time on the block for sold cars (t=-1.62)

C: Residual price and time on the block for sold cars (t=-2.52)

Figure 5 – Correlation of Performance Measures with Subjective Evaluations. The panels below provide scatterplots that show the correlation in fixed effects for 41 auctioneers between the company’s subjective evaluations (on a 0 to 1 scale) and probability of sale, residual price, and time on the block for sold cars. All fixed effects come from the fully specified model within seller, auction day and time of day, lane, and car types. Fitted lines are reported as well as the t-statistic from univariate regressions between the subjective evaluation and each performance measure.

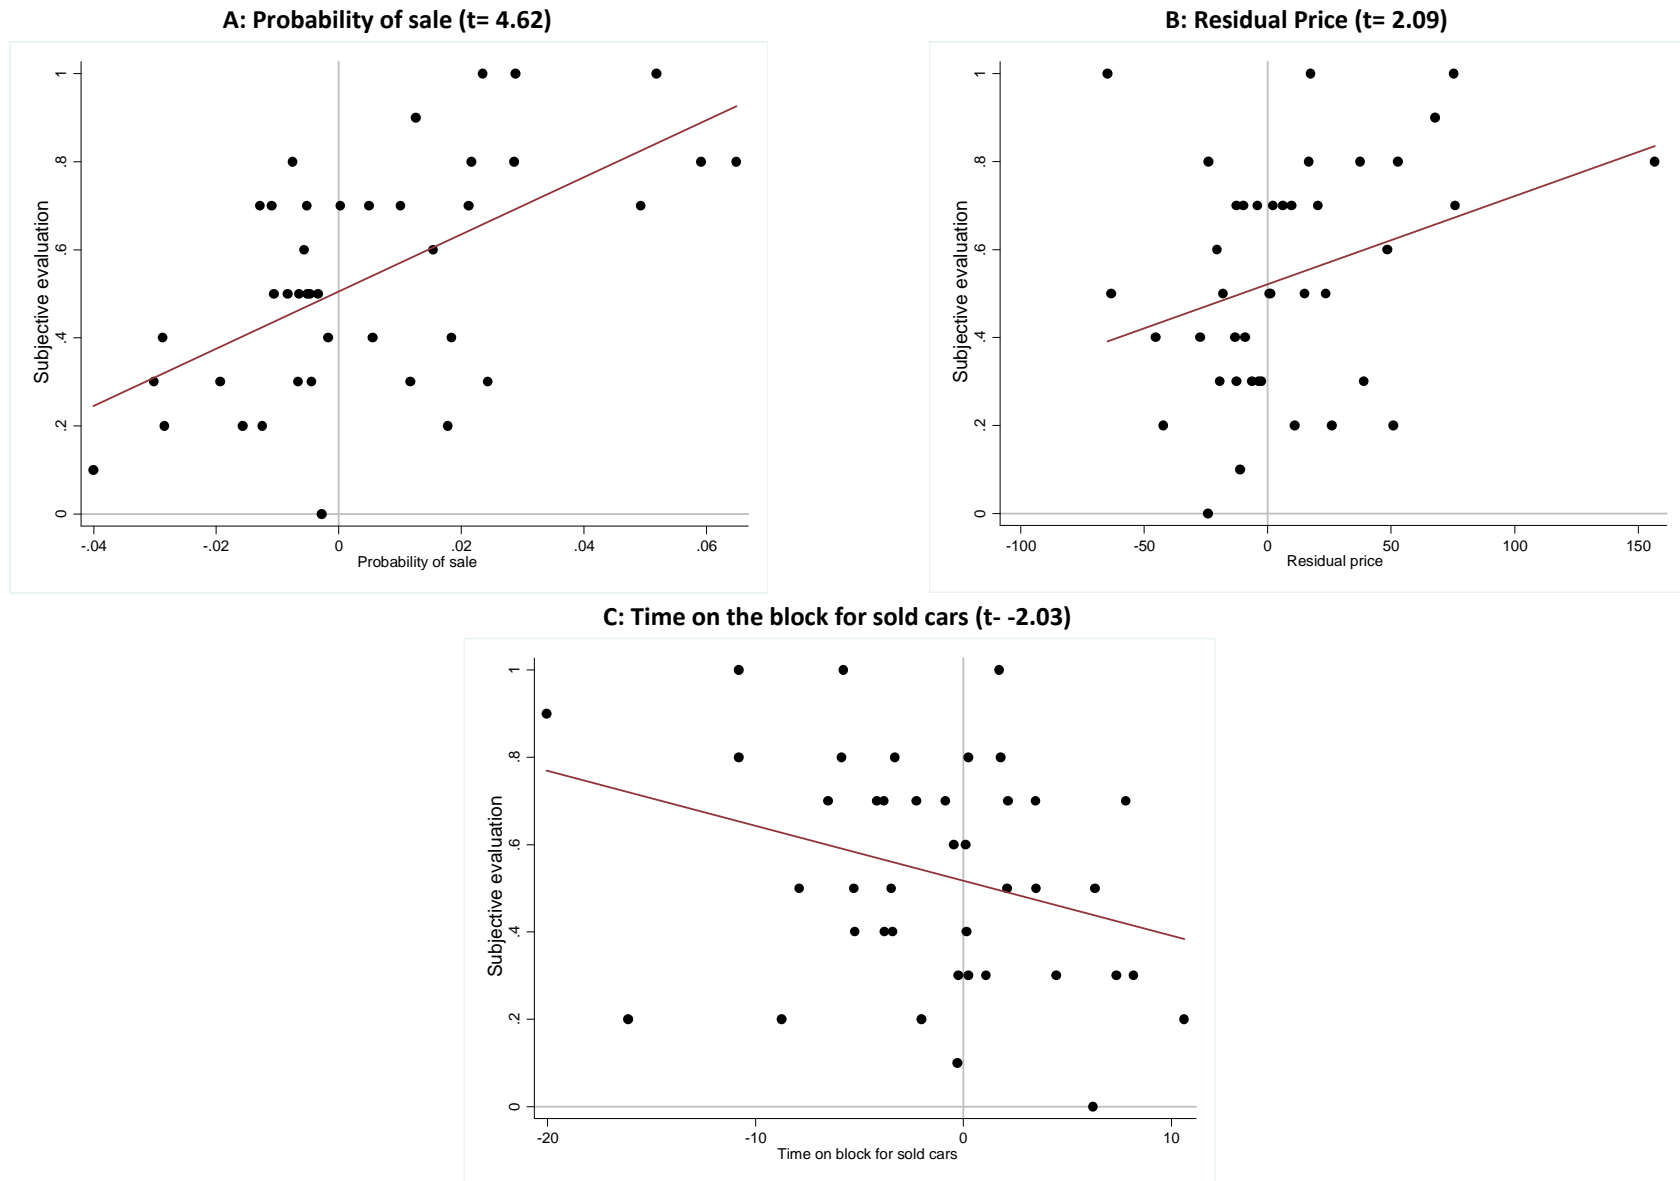

Figure 6 – Performance rankings for auctioneers still at the company in 2012 and auctioneers who left the company by 2012. The estimated auctioneer fixed effects are obtained from the fully specified regression model with seller fixed effects, auction day and time of day, lane fixed effects, and car type fixed effects, distinguishing between auctioneers who were still at the company by the end of 2012 (Stayers, $N=41$; black filled in dots) and those who left by between the end of 2008 and 2012 (goers, $N=18$, red empty dots).

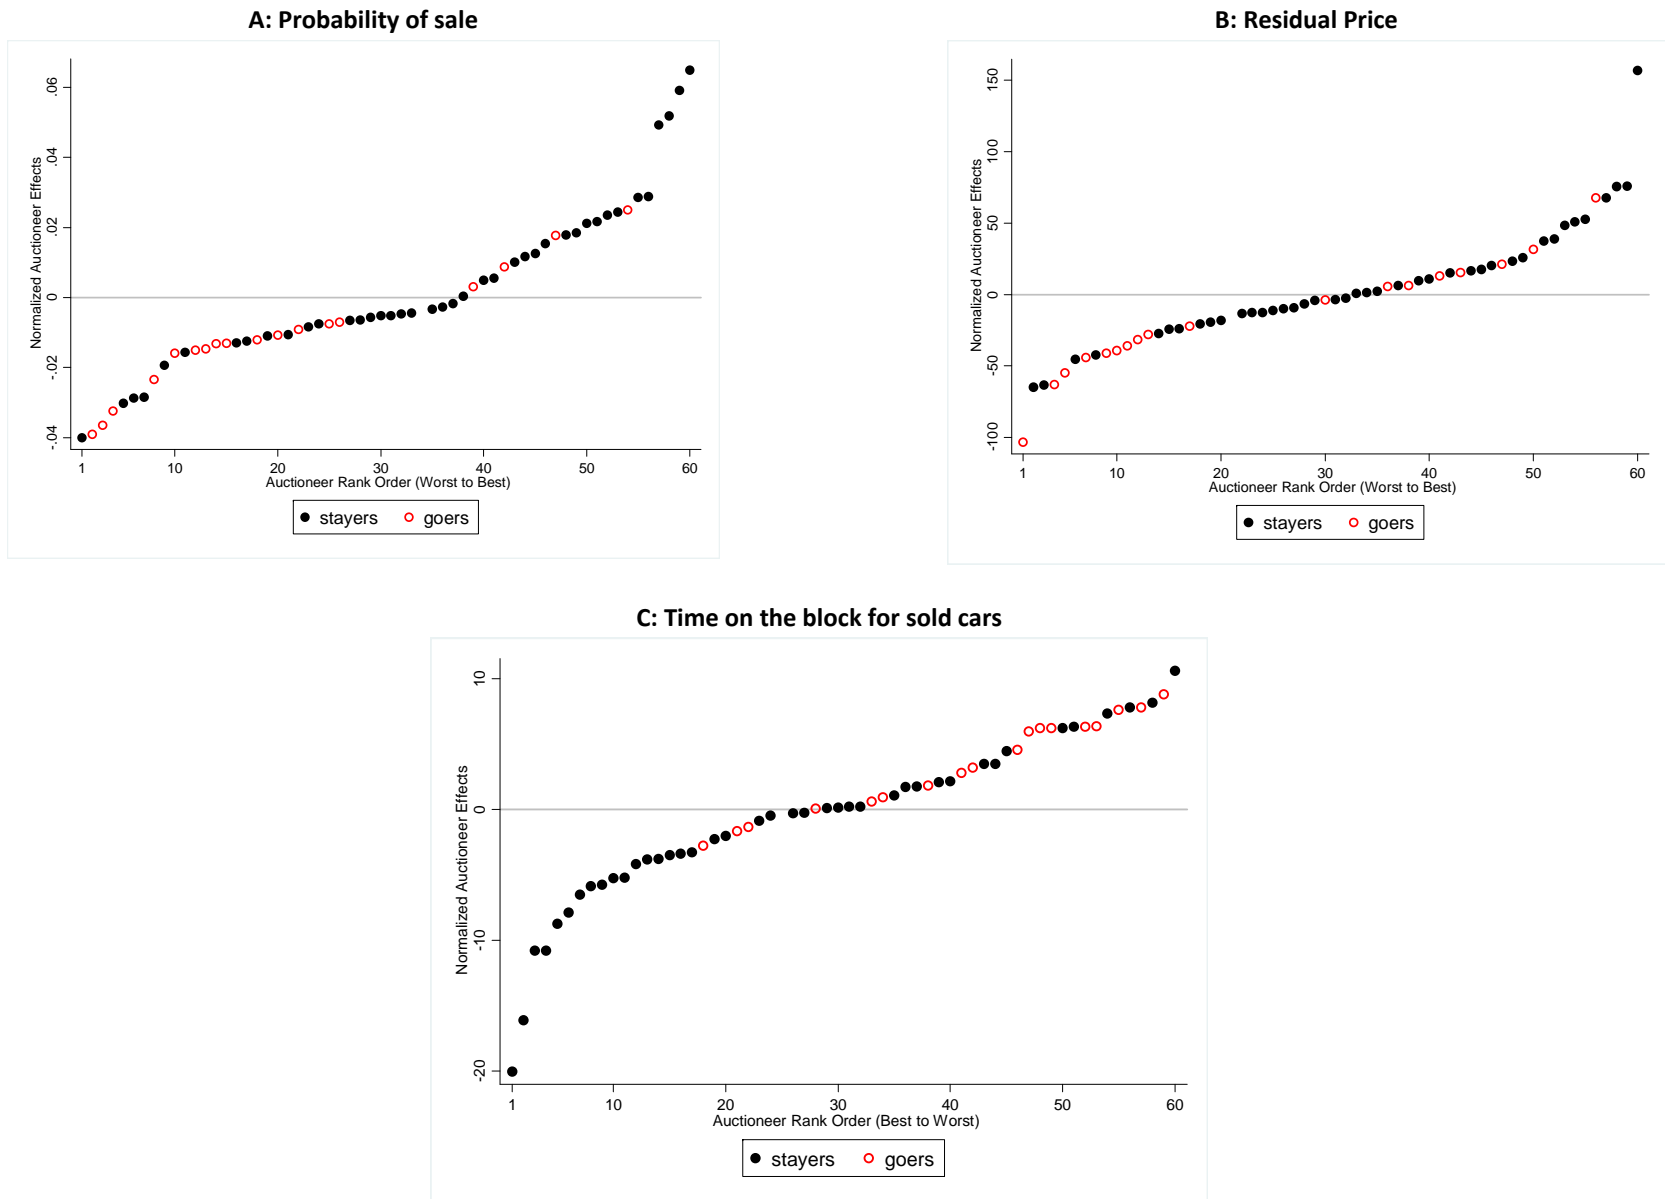

Figure 7 - Survey results. This figure reports the average ratings received by various proposed answers to a question asking auctioneers to rate the importance of tactics for determining a "highly effective" auctioneer (from 0-lowest to 5-highest):

Table 1: Descriptive statistics

	Observations	Mean (Std. Deviation)
Share of cars sold	859,240	0.53 (0.50)
Sale price (\$)	455,224	15,140.97 (9567.57)
Price - Expected Price (\$)	424,852	377.24 (1669.43)
Time on the block (s)	777,960	103.18 (74.03)
Age (years)	859,239	4.43 (3.28)
Miles	859,240	56,236.51 (33,730.87)

Table 2: Standard deviations of estimated auctioneer effects with varying controls. This table displays the effect of a one-standard-deviation increase in auctioneer performance as measured by the probability the car sold, residual price, and the time on the block. Each cell of the table comes from a separate regression on auctioneer fixed effects and varying degrees of controls as specified. In addition to the standard deviation, the second column for each outcome measure reports the coefficient of correlation between two consecutive specifications, and, in brackets, the t-statistic on the coefficient estimate from a linear regression of the estimated auctioneer effects from each specification on a constant and the auctioneer effects from the subsequent specification.

	Probability of sale		Residual price		Time on block	
	Standard deviation	Coefficient of correlation with previous specification	Standard deviation	Coefficient of correlation with previous specification	Standard deviation	Coefficient of correlation with previous specification
1 Raw values	0.051		219.633		7.48	
2 Seller FEs	0.038	0.94 [21.46]	55.842	0.67 [6.89]	5.77	0.95 [24.31]
3 Seller, time of day, auction day FEs	0.025	0.73 [8.19]	52.559	0.61 [5.88]	5.75	0.81 [10.74]
4 Seller, time of day, auction day, lane FEs	0.023	0.97 [31.44]	40.274	0.86 [13.14]	5.00	0.98 [36.59]
5 Seller, time of day, auction day, lane, make FEs	0.023	0.99 [106.33]	40.963	0.99 [49.65]	5.26	0.99 [79.07]
6 Seller, time of day, auction day, lane, make*age FEs, miles	0.024	0.99 [122.8]	41.864	0.98 [42.74]	5.23	0.99 [510.73]
7 Seller, time of day, auction day, lane, make*model*age FEs, miles	0.023	0.99 [123.26]	41.619	0.99 [52.11]	5.23	0.99 [289.38]
8 Seller, time of day, auction day, lane, make*model*age*body FEs, miles	0.023	0.99 [139.15]	41.776	0.98 [38.39]	5.23	0.99 [231.28]

Table 3: Survey results from role-of-auctioneer question

Question: <i>“If you had to pick one of the statements below, which one do you think best describes the most important role of auctioneers at [company’s] auctions?”</i>	
Option	Number of respondents choosing option
1 Auctioneers create a sense of excitement, competition, and urgency among buyers that encourages more bidding	31
2 Auctioneers provide expert information about cars on the block that bidders do not know themselves	1
3 Auctioneers persuade sellers to accept the fair market price	1
4 Buyers know what a car is worth and will bid accordingly. Therefore, auctioneers do not have a large impact on auction outcomes	0

Appendix
