Chapter pages in book: (p. 155-224)

# Differential Fertility in United States Census Data <br> RICHARD AND NANCY RUGGLES <br> YALE UNIVERSITY 

## Summary

The rate of population growth in the United States has in the past been strongly influenced by three high fertility groups. These groups are farmers, the foreign born, and the urban native born of lower education. The rapidly falling birth rate since 1900 has been due in large part to the gradual attrition of these groups, and to a lesser extent to falling fertility within the groups themselves. Farmers and foreign born are now a much smaller proportion of the total population, and cannot be expected to have as much influence on the growth of the population in the future as they have had in the past. It is the fertility of the urban native born group which holds the key to future population growth.

This study; made possible by a grant of the Milbank Memorial Fund, analyzes a differential fertility sample of North Central United States obtained in conjunction with the 1940 population census. The study is restricted to urban native women of native parentage, married once to native men of native parentage, aged 40-70. For this group, the number of children ever born was examined in relation to (1) woman's education, (2) husband's education, (3) husband's wages, (4) husband's occupation, (5) size of city, (6) woman's marriage age, and (7) woman's age. The analytic procedure adopted involved the examination of differences between the average family size of different classifications of women, testing the statistical significance of this difference both for individual comparisons of cells and for groups of such comparisons.

It must be noted at the outset that this study is purely descriptive. It does not test any hypotheses; it merely describes the differences in family size observed in the data. Descriptive studies such as this, however, may be useful to investigators who are attempting to formulate hypotheses which they in turn will test against other bodies of data. Also, the data examined were obtained almost twenty years ago. This fact does not, of course, invalidate the observations, but it does mean that they may not be pertinent to women who are now of childbearing ages. On the other hand, it is entirely too cavalier to disregard the evidence of these data on
this ground. The fact that the data were collected in 1940 is in itself of no particular significance; the childbearing years of the women covered extend from 1890 to 1940 , and, by examining women of different ages, time trends in family size for different groups can be analyzed.

Examining the relation of family size to woman's education, the familiar inverse relationship was observed up to the four year high school level. In comparing women of four year high school education with women of one year college or more, however, the situation differed. The families of the high school women were larger in circumstances where the husband either had less education or was in a low wage or occupation group. Where the husbands had more education, or were in a high wage or occupation group, however, the college women had larger families.

Husband's education, like woman's education, was also inversely related to family size up to the four year high school level. When examined within woman's education or husband's occupation classes beyond this point, a positive relationship emerges. When examined within husband's wage classes, however, this positive relationship does not appear, strongly suggesting that income is the factor which produces it.

The strong inverse relationship also appears for the lower occupation classifications. When examined within some variables (such as woman's education and husband's education), a positive relationship again appears between the top two occupational groups. This positive relationship does not appear when the relation with occupation is examined within husband's wage groups, again strongly suggesting that the positive relationship is due to income.

In view of the manner in which these positive relationships of family size with the other variables at the higher socio-economic levels tend to disappear when examined within husband's wage groups, special attention was given to the analysis of husband's wages. There are some indications in the general tabulations of a positive relationship between family size and husband's wages at the higher wage levels when the examination is made within woman's education or husband's education, but the relationship is weak, and does not appear when wages are examined within occupational groups. To examine the question in greater detail, a special tabulation was made of the relation of family size to wages for women with four year high school education or more married to husbands of four year high school education or more, subdivided into three occupational groups. A separate special tabulation was also available for a sample of college graduates collected by Time Inc. These special tabulations did not bear out the contention that family size is positively related
to income at higher socio-economic levels. However, the inverse relationship between husband's wages and family size characteristic of the lower groups also disappeared.

Thus, this examination seems to indicate that for lower socio-economic levels there is in fact a highly inverse relationship between family size and socio-economic status, no matter how this status is measured. However, for higher socio-economic levels this inverse relationship disappears, and seems to be replaced by a fairly weak positive relationship, which cannot be attributed specifically to any single factor. Woman's education, husband's education, income, and occupation all make some slight contribution, but the relationship for any one of them alone is so weak that it does not rise above the noise of the random disturbing factors.

In conclusion, therefore, it would seem that as the income and education of the general population increase, the differences in family size of different groups will become smaller and the population will become very much more homogeneous with respect to family size. It may then be that changes in the composition of the society will become less important in determining population change than changes in desired sizes of families. While it is still true that wars, depressions, and other unusual circumstances will affect the timing of births, and therefore family size for specific cohorts, there will nevertheless be greater stability in average family size in future years than there has been in the past.

The basic reason for studying population growth is of course in order to be able to throw some light upon the future development of our society. As far back as Malthus, fairly elaborate theories were formulated regarding the path which population growth might be expected to follow. At the present time interest in the subject of population growth is sufficient so that estimates of future developments are continually being made, by a number of different methods. Some of these estimates are direct extrapolations of general population growth trends, but others do try to take into account the interactions between population growth and various other facets of our society. Before any accurate-or any useful-extrapolations can be made, a clear understanding of these interactions is essential.

## THE EFFECT OF POPULATION GROWTH UPON THE ECONOMY

To consider first the effect of population growth upon the economic development of the society, it is obvious that the pattern of population growth is a prime determinant of the pattern of both economic needs and
economic resources. For example, a rapidly growing population will have a larger proportion of people in the younger age groups, and a declining population a larger proportion in the older age groups. This will affect not only the demand for housing and other consumer goods, but also the need for such things as education and old age assistance, and the nature of full employment policy. One of the prime requisites of city planning is to foresee what the future population will be, so that the present development of cities will meet future needs. An accurate estimate of future population size and composition is therefore basic to planning the type and magnitude of investment both by private enterprise and by government. It is important to know how many people will share the natural resources of the country, become consumers, and enter the labor market.

## THE EFFECT OF SOCIAL CHANGE UPON POPULATION GROWTH

The relationship between population growth and other factors in the society is of course not one-sided. Population growth is in turn strongly influenced by social change. For instance, the influence of increasing industrialization is well recognized. When the majority of the population lived on farms the advantages of large families in farming strongly influenced family size. As urbanization progressed, the declining advantages of large families were reflected in a declining rate of population growth. Similarly, there are other social changes which it is possible to foresee. The standard of living will probably continue to increase, and there will be foreseeable changes in the distribution of income, of occupations, and of the level of education. Any realistic population projection must take such factors as these into account. In order to do so, it is necessary to make an evaluation of what their impact is likely to be.

In evaluating this impact, it is useful to consider two types of effect. First, the birth rate within relatively homogeneous groups may change. The term "homogeneous" as used here means people with similar social and economic characteristics. Second, the relative size of different groups may change, and therefore the weights to be attached to their birth rates may also change.

With respect to the first of these effects, it is of course reasonable to expect that groups of families with similar socio-economic status will have a similar distribution of numbers of children-or else there is no point to the analysis. At the same time, however, it is impossible as a practical matter so to specify the characteristics of the individual groups that their
birth rates will not change over time. A great many factors which do influence the birth rate cannot be taken into account. A farmer, for instance, is not the same today as he was in 1900-among other reasons, because of the introduction of mechanization, which reduces the necessary labor supply and thereby changes the large family from an earning asset to an expense. It is therefore bound to reduce the pressure for large families in this group. If increasing farm mechanization is expected to reduce the need for labor still more in the future, the birth rate of farm families may be expected to fall further, but if mechanization is not expected to have much more effect, there should be no further influence upon the birth rate from this source. In this way, making allowance where possible for factors that are likely to have an influence but cannot be separated out, an estimate of the expected development of the birth rate for each group can be derived.

The second effect derives from factors which change the relative importance of the various groups in the population by some means other than changes in their birth rates. Such factors include industrialization, with its accompanying migration from the farms to the cities; the cessation of immigration, with the resulting smaller number of foreign born; and rising standards of education. The influence of each of these factors must be appraised, so that the composition of the population at some future date can be estimated. Combining these two elements, an estimate of aggregate population growth can be derived by applying the birth rates expected for each sector to the expected future composition of the population, and the total growth of the whole population estimated by adding together the growth in each sector.

Population estimates made by this method may differ markedly from estimates derived from a simple extrapolation of the general rate of population growth. Different groups in the population have widely different birth rates, and as the relative importance of these groups changes, so also will the average birth rate. The fact that the birth rate of a society has steadily decreased does not mean that it will continue to decrease even though the same general trends for individual groups continue. Suppose, for example, that the importance of certain high fertility groups, such as the foreign born or farmers, declines. The over-all rate of growth will decline even if birth rates within each sector of the economy do not change. As the trend continues, however, the decline in the average birth rate due to this cause will fade into insignificance as these groups become a smaller and smaller proportion of the total population.

## THE PURPOSE, ORIGIN, AND NATURE OF THE PRESENT STUDY

This study is not intended to lead to any general population theory or to provide the tools necessary for forecasting population growth. Nevertheless, it is conceived within the framework discussed above. Its attention is focused on one aspect of the problem, specifically, the analysis of differential fertility in terms of education, income, and occupation, for a particular population group.

The origin of the present investigation goes back to work originally started just prior to World War II, and summarized in an unpublished report in 1947. This earlier study used as basic data a sample of 50,000 cases collected from maternity hospitals in Boston and New York, and a sample of 8,000 college graduates collected by Time Inc., in 1940. It focused on the relationship between income and family size.

In examining the samples obtained from the various hospitals, it was found that groups similarly defined derived from different hospitals had significantly different numbers of previous children per thousand women. This suggested that there were probably differences in the type of patient to whom the various hospitals catered. Although the study was confined to native born women, it is probable that some hospitals had a larger proportion of women whose parents 'were not native born than other hospitals. Furthermore, there were known to be religious differences among the hospitals. In any event, whatever the cause for the differences between hospitals, it was evident that adding all the cases together would yield conclusions dependent mainly on the size of the samples from the various hospitals, rather than on any true relations existing in the population as a whole. For this reason, the data for each hospital were examined separately.

Because the data were lacking in reliability and validity, they did not support any definitive answer with respect to the relationship between income and family size. There was no instance in which a reliable negative relationship between income and family size was found for groups homogeneous in other respects, and the few groups for which the data were most reliable and valid generally yielded positive relationships. On the other hand, a negative relationship may well have existed for the groups in which the reliability of the sample was too low to permit analysis. The best evidence, however, was in conflict with the traditional view of the relation between income and family size. 'The evidence in itself was far from conclusive, but it pointed to the desirability of further study of this question.

The differential fertility sample obtained by the Census Bureau as a
part of the Census of 1940 offered a possible source of additional data. The experience with the hospital data pointed to the desirability of obtaining as much homogeneity in the groups analyzed as possible. One way to accomplish this was to omit from the analysis groups which in themselves were of marginal interest or which were too complex or of insufficient size to yield valid conclusions. In the context of the Census data, the foreign born constituted such a group, which seemed better eliminated. On the one hand, the variance among the foreign born themselves, in terms of family size, was very considerable. Previous studies had shown that immigrants born in northern Europe tended to behave quite differently from those born in southern Europe. By 1940, furthermore, the number of foreign born of childbearing ages was rapidly decreasing, and given the existing immigration restrictions it promised to be a factor of minor importance in the future. The farm population, similarly, has been a declining element in the picture, and the analysis could be considerably simplified by restricting it to urban families. Also, in order to reduce the complexity of the study, the analysis was restricted to one region of the country, since different regions might well differ in fertility patterns. Finally, in order to be able to deal with number of children ever born rather than with birth rates, the study was restricted to completed families. In this way, problems relating to differences among groups in such factors as marriage age and spacing of children could be avoided, and final family size used as an indicator of fertility over the childbearing age.

On this basis, an intensive analysis was undertaken, with the generous support of the Milbank Memorial Fund, of differential fertility of nativewhite women of native-white parents married to native-white men of native-white parents, urban, aged $40-70$, married once and husband present, living in North Central United States. When these criteria were applied to the Census sample, the available number of cases came to 40,000. A breakdown of the total population in North Central United Sitates and the sample is shown on p. 162.

The punchcards are for a 5 per cent sample in some areas and a $2 \frac{1}{2}$ per cent sample in other areas; the punchcards for the $2 \frac{1}{2}$ per cent sample were duplicated by Census to bring them to a level comparable with that for cards from other areas. Hence computed sampling variances will be too small in many cases, depending as they do on some duplicated punchcards.

Another source of bias is the exclusion of women with no report on children ever born. There is evidence that in 1940 a disproportionately

| A. All women aged 15-70 | 15.0 | 750 |
| :---: | :---: | :---: |
| Minus: Single women | $-4 \cdot 3$ | -215 |
| B. Equals: Women ever married | 10.7 | 535 |
| Minus: Husband not present | -3.2 | $-160$ |
| C. Equals: Women husband present | $7 \cdot 4$ | 375 |
| Minus: Women aged 15-40 | $-3.3$ | $-165$ |
| D. Equals: Women aged $40-70$ | 4.2 | 210 |
| Minus: Rural women | -2.0 | -100 |
| E. Equals: Urban women | 2.2 | 110 |
| Minus: Women having either parent foreign born or husband with either parent foreign born | -1.4 | -70 |
| F. Final selection | 0.8 | 40 |

large number of the women with no report on children ever born were childless. Evidently the enumerators sometimes left the item blank for childless women instead of entering zero. Approximately in per cent of the ever-married women sampled were recorded as not reporting on children.

At the time this study was undertaken, the only equipment available was a punchcard sorter and a hand calculator. As a result, the analysis proceeded slowly and painfully over a two-and-a-half-year period. The present paper is a discussion and analysis of the data which emerged.

## GENERAL METHODOLOGY

The methodology employed in this study was conditioned both by these technological considerations and by the need to develop statistical procedures which did not entail unduly restrictive assumptions. Regression analysis might have seemed the logical approach. However, both the earlier study of hospital data and other available studies on this topic strongly suggested that the problems of lack of linearity in the regressions and co-variation among the major variables would seriously weaken the suitability of linear regression analysis. More complex forms of multivariate analysis were beyond the computational resources available at that time.

For these reasons, a simple and straightforward procedure was adopted. The sample data were classified into homogeneous groups according to the following characteristics: (1) age of woman, (2) education of woman, (3) education of husband, (4) husband's wages, (5) husband's occupation, (6) size of community, and (7) woman's marriage age. Tabulations of number of women and number of children ever born were then made showing cross-classifications of pairs of these variables and woman's age, such that differences over time in the relationships between these pairs of variables could be examined. Thus the following 15 cross-classifications of number of women and number of children ever born were developed, all of them additionally cross-classified by age.
i. Woman's Education and Husband's Education
2. Woman's Education and Husband's Wages
3. Woman's Education and Husband's Occupation
4. Woman's Education and Size of Community
5. Woman's Education and Woman's Marriage Age
6. Husband's Education and Husband's Wages
7. Husband's Education and Husband's Occupation
8. Husband's Education and Size of Community
9. Husband's Education and Woman's Marriage Age
io. Husband's Wages and Husband's Occupation
I 1. Husband's Wages and Size of Community
12. Husband's Wages and Woman's Marriage Age
13. Husband's Occupation and Size of Community
14. Husband's Occupation and Woman's Marriage Age
15. Size of Community and Woman's Marriage Age

These tabulations are presented in the Appendix.
The question could now be posed whether, within cross-classifications of this sort, family size differed significantly from group to group. The obvious approach to this question would have been through conventional variance analysis. But here again, the earlier studies suggested that this procedure would have serious limitations for the kinds of questions we were trying to answer. Variance analysis could only show whether a given cell differed significantly from the average of all other cells in a given group. It could not, for instance, adequately handle such questions as whether the relationships between variables were continuously increasing throughout the range of variation. For this reason, a somewhat different technique was resorted to. Differences in family size between adjacent cells in the tables shown in the Appendix were examined for significance and direction. Where a series of differences between adjacent
cells were significant and of the same sign, it suggested that a significant and consistent relationship existed between changes in the variables being examined and family size.

The number of possible comparisons between adjacent cells in the fifteen tables is very large. Since the tables in the Appendix are three-way cross-classifications, comparisons between adjacent cells can be made in three directions. This is shown in the diagram below; cell A can be compared with cells $B, C$, or $D$ by altering each of the three variables in turn.
A. Woman aged $40-44$;

Education grade 6;
Husband's education grade 6
C. Woman aged 45-49;

Education grade 6;
Husband's education grade 6
B. Woman aged $40-44$;

Education grade 7-8;
Husband's education grade 6
D. Woman àged 40-44;

Education grade 6;
Husband's education
grade 7-8

In all, about 8,500 comparisons would be possible in the fifteen tables. However, many of the cells are empty, and many others contain only a very small number of cases. In order to economize on computational effort, these cells where the sample was too small to be likely to yield significant results were omitted from the analysis. An arbitrary cut-off point of 100 cases was adopted; no comparisons were made for cells containing a smaller number of cases. In a few instances, comparisons were made between non-adjacent cells where the immediately adjacent cell had less than roo cases but the next cell was larger. However, these non-adjacent comparisons do not enter into the final analysis. On this basis, about 3,0oo comparisons were made.

For each pair of cells that were compared, the significance of the difference between the means of family size was computed. The results of these computations were expressed in standard error units. Hereafter this measure will be referred to as $\tilde{\mathrm{D}}$. The size of $\tilde{\mathrm{D}}$ is dependent upon three factors: ( 1 ) the variance within the cells being compared; (2) the number of cases in each of the cells being compared; and (3) the magnitude of the difference between the means of the cells. Thus a high value for $\tilde{\mathrm{D}}$ may come about either through a large difference between means or through a much smaller difference between the means accompanied by smaller variances and larger sample sizes. It should be emphasized that $\tilde{\mathrm{D}}$ does not measure the magnitude of the difference between means. What it does measure is the significance of a null hypothesis as the
explanation for the observed difference between the means. The table below illustrates the probabilities that can be attached to various magnitudes of $\tilde{\mathrm{D}}$, that is, the likelihood of a given $\tilde{\mathrm{D}}$ occurring through chance if there is in fact no difference between the true means. ${ }^{1}$

The tables in the Appendix are extremely useful in examining questions at a highly detailed level, but neither they nor the D̃'s directly computed from them readily lend themselves to summarization or generalization. The procedure finally adopted for summarizing the D's is basically a simple one. It is based upon the principle that if for any group of comparisons the null hypothesis is valid, the sample D̃'s with signs attached should be normally distributed about the central value of zero. The means of the D's for groups of comparisons were therefore computed, and the significance of their difference from zero in turn computed. This statistic, equal for any particular group of $\tilde{\mathrm{D}}$ 's to $\frac{\sqrt{\mathcal{N}} \Sigma \tilde{\mathrm{D}}}{\mathcal{N}}$ where $\mathcal{N}$ equals the number of comparisons, will be referred to hereafter as $\tilde{\mathrm{S}}$. It provides a measure to which the probability table shown above also relates, since it measures differences of the means of $\tilde{\mathrm{D}}$ from zero in standard error units. Again it should be emphasized that the magnitude of $\tilde{S}$ is not a measure of the magnitude of the mean of the D's, since consistent and reliable small values of $\tilde{\mathrm{D}}$ will yield large $\tilde{\mathrm{S}}$ 's, just as consistent and reliable small differences between cell means will yield large D̃'s. As the probability table shows, differences in values of $\tilde{D}$ and $\tilde{S}$ above the level of 3 or 4 mean very little in terms of probability.

Table i below shows the D's and S's which result from comparing women of different educational levels within specific husband's educational levels. In addition to the D̃'s and S̃'s, the absolute difference in

1 The biases resulting from (1) duplicated punchcards and (2) the erroneous classification of childless women will of course impair the validity of D as a measure of significance.
TABLE
Differences in Woman's Education within Husband's Education

| Wife's Education | Husband's Education |  |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

family size is also shown in the columns labeled $m_{2}-m_{1}$. In this case $m_{2}$ refers to the women with higher education and $m_{1}$ refers to the women with lower education. It will be noted that many of the cells in this table are vacant. This results from the fact that there were too few cases of the given characteristics in the sample to yield reliable results. For example, women of sixth grade education married to husbands having more than three years of high school could not be compared with seventh to eighth grade women with similar husbands, because there were not enough cases. This, of course, has significance for the S's. The S̃'s are an aggregation of D's, and will reflect only those D's which are available. In many instances this will mean that the S's for a specific comparison will represent only the younger age groups where the number of women in the sample is larger. The same is also true in aggregating the S's to combined relationships: only those S̃'s which are actually available can be combined. In Table i, for instance; for the comparison between sixth grade and seventh to eighth grade women, only two S's are available. These refer to women whose husbands have sixth grade education, and to women whose husbands have seventh to eighth grade education.

Tables similar to Table i could also be drawn up to show the relationship of family size to woman's education within each of the other variables, viz., husband's wages, husband's occupation, size of community, and woman's marriage age. In all, thus, five tables of the form of Table i would be required to describe the relationships found in the Appendix Tables relating to woman's education. Another set of five tables would be required to describe the comparisons of family size for husbands of different education, another set of five for husbands of different wages, and so on. In all, 30 tables of the form of Table 1 would be needed to show all the D̃'s. In order to condense the presentation, the S's have been extracted from these tables and arranged in the set of six tables in the following text. The S's in Table 1 , for example, appear in section A of Table 2. Each section of Table 2 summarizes the comparison of family size of women of different education within one of the other variables; thus section A refers to comparisons of family size of women of different education within husband's education; section B, to comparisons of family size of women of different education within husband's wages, and so on. Table 3 summarizes all of the comparisons of family size of husbands of different education; Table 4 , comparisons of family size of husbands of different wages, etc.

Although the comparisons in these tables take the age of woman into account insofar as they make comparisons only within one age group, the
effect of age itself is not shown. For this purpose it is necessary to compare women of a given age with a specific set of characteristics with women of another age having the same characteristics in other respects. Thus, women of age $40-44$ having sixth grade education married to men of sixth grade education can be compared with women of age 45-49 having sixth grade education and married to men of sixth grade education. These comparisons can be made between four adjacent age groups for each of the 15 tables in the Appendix. They can be summarized in much the same way that Table 1 was summarized in Table 2, by computing S's for the combined relationship. This has been done in Table 8.

## WOMAN's EDUCATION

The familiar generalization that the higher the woman's education the smaller the family size is borne out by Table 2. Here the S's for the combined relation are generally high, and the direction of the difference is usually negative, indicating an inverse relationship. This inverse relationship between woman's education and size of family is well known, but examination of the specific comparisons as shown in Table 2 provides considerably more information. The magnitude of the S's and the signs of the differences indicate precisely where the inverse relationship holds.

Up to four years of high school, the inverse relationship between woman's education and family size is valid. However, in the comparison of four year high school women with women with one year or more of college, there are a number of instances where direct positive relationships between family size and education appear. To discuss this situation further, it will be useful to examine the different sections of Table 2 in greater detail.

Husband's education. Within husband's education, the inverse relation between the level of the wife's education and family size holds for all groups except four year high school and college women married to college men. In this instance a positive relation appears, suggesting that the more highly educated women have somewhat larger families. It should be noted, however, that the more highly educated women do not have very much larger families, and the $\tilde{S}$ is not highly significant.

Husband's wages. Within husband's wages, the inverse relation between the level of the wife's education and family size holds, except for four year high school and college women married to men having wages of $\$ 5,000$ or more. Here a positive relation between education and family size appears, indicating that at the highest income and education levels the relation between family size and woman's education is direct.

Husband's occupation. Within husband's occupation, the inverse relationship between education and family size holds only below four year high school education. Comparing four year high school women with college women, a positive relationship between woman's education and family size was found for all groups except women married to professional men. Here an inverse relationship of some significance persists.

Size of community. Within size of community, a quite strong inverse relationship between woman's education and family size exists for woman's education levels below four year high school. In the higher educationa] levels, the situation is less clear, with both positive and negative relationships appearing. These relationships could be accounted for by causality running from number of children to size of community, rather than the reverse: more highly educated people of higher incomes who have large families may have more tendency to move away from large cities than do either people of similar family size in lower socio-economic groups, or people of similar socio-economic groups with small families.

Marriage age. Within marriage age, it appears that for early marriages (before age 24) college women have more children than high school women. If they marry after age 24 , however, the high school women have more children.

In summary, it would appear that the inverse relationship between woman's education and family size holds generally up to four year high school education. 'In comparing women with sixth grade education or less with women of seventh to eighth grade education, the difference is quite large. Smaller differences appear when comparisons are made between women of seventh to eighth grade education and women with one to three years of high school, and between one to three years of high school and four years. In the comparison of four year high school women with college women, the inverse relationship is not always present.

## HUSBAND'S EDUCATION

In broad outline, the observations made about the effect of changes in woman's education on family size hold also for changes in husband's education. As Table 3 shows, the relationship between husband's education and family size is generally quite significant, and the direction is inverse. As in the case of woman's education, however, it is also evident from Table 2 that the comparison of husbands of four year high school and college education exhibits characteristics different from those found at other levels of husband's education.

Within woman's education, the comparison of the family size of men
with four year high school education with that of college men yields S's which are positive and significant, for all but one level of the wife's education (one to three years of high school). In the discussion of the effect of differences in woman's education on family size above, it was noted that when four year high school and college women married husbands of lower education the high school women had larger families than the college women, but that when they married men of college education, college women tended to have larger families than the high school women. For husbands, it is found that even when the men are married to women of four year high school education the college men tend to have larger families than high school men.

Within husband's wages, no significant relationship emerges from the comparison of four year high school men with college men, even though in several instances the direction of the difference is negative. In contrast with the data shown in Table 2 for woman's education, these data exhibit somewhat stronger positive relationships and weaker negative relationships.

Within husband's occupation and within size of community, the S's for the comparison of four year high school men with college men are positive but not highly significant. In the case of husband's occupation the differences were found to be positive in all cases except for professional men. This same result was found in the examination of woman's education within husband's occupation. Within size of community college men generally have larger families than four year high school men, but the relationship is mixed and rather weak. As was suggested above in the discussion of size of community and woman's education, there may be intercorrelations between family size and subsequent choice of community which affect the total relationship.

Within woman's marriage age a consistent positive relation appears in the comparison of four year high school and college men. Although this means that with a given wife's marriage age, college men have larger families than four year high school men, it does not follow, of course, that college men as a group have larger families. To the extent that men of four year high school education marry younger, and thus have younger wives, this effect may offset or more than offset the other tendencies.

## HUSBAND'S WAGES

The combined relation between husband's wages and family size is generally inverse when measured within wife's education, husband's education, husband's occupation, size of community, or woman's marriage

age. The inverse relationship is most pronounced at lower income levels and for the lower socio-economic groups. At higher income levels or in higher socio-economic groups the inverse relationship may disappear, and in some cases a positive relationship between income and family size emerges. However, there is no distinct pattern, so that the most that can be said on the basis of the information in Table 4 is that at the higher income levels income does not appear to be an important element.

Because of the unevenness of the evidence with respect to the higher ranges of income, a special tabulation was made to obtain greater homogeneity in the educational and occupational classifications. To this end, a sub-sample of women of four year high school education or more with husbands of four year high school education or more was selected from the original sample. Within this sub-sample three occupational groups -clerical, proprietor, professional-was examined separately. Two ages of women were distinguished-forty to forty-four and forty-five to fortynine. Within these highly specified groups, the relation between income and family size was examined. In addition, a special sample of college graduates was obtained from Time Inc. The special tabulation of the census sample contained about 3,400 cases and the Time sample about 1,000 cases. The result of these tabulations, with the corresponding D's and $\tilde{S}$ 's, is shown in Table 5. For these special tabulations as a group, S comes out between 0.80 and 0.98 , depending on how the $\tilde{\mathrm{D}}$ 's are aggregated. Although the sign of the difference between the means is positive, the $\mathbb{S}$ is too small to be considered very significant. Of the 25 differences between the means that could be computed, 13 differences were positive and 12 were negative. For the 11 comparisons in which $\mathfrak{D}$ was greater than 1 , six were positive and five were negative. Examination of the S's for the individual rows or columns of D's does not reveal any striking relationships. The Time sample does show more significant D's at the highest income levels. However, it must be recognized that this sample is not as homogeneous as the census sample, and no such relationship emerges there. Such things as education of wife, occupation, region, and parentage of husband and wife are not specified in the Time sample, and they may well be different for different income levels.
husband's ogcupation
Although the combined relationship between the occupational level of the husband and family size is generally inverse, this relationship does not hold between all pairs of occupations (see Table 6). It is strongest between craftsmen and clerical workers and highly significant between
laborers and service workers. In the comparison of service workers with operatives and of operatives with craftsmen, direct relationships as well as inverse relationships appear in specific instances. Evidence of even stronger direct relationships appears for the comparisons of clerical workers with proprietors and proprietors with professionals. In a number of these instances, strong positive relationships can be found, and especially in the proprietor-professional comparison, the inverse relationships that do exist are not highly significant.

Thus the combined inverse relationship for occupation groups is mainly due to the comparisons of laborers with service workers and craftsmen with clerical workers. In comparing proprietors with professionals, it is generally found that professionals had the larger families.

## size of community

As was suggested above, although the size of community in which one lives may affect the size of one's family, it is obvious that the size of one's family is also likely to influence the size of the community in which one lives. Because of the interdependence between these two factors, it is difficult to attach much analytic meaning to the observed differentials in Table 7. However, it may be useful to describe the relationships which are found. In general the relationship between size of community and family size is inverse and quite significant. There is one exception, however. There does not appear to be a significant difference in family size between communities of $2,500-5,000$ and communities of $5,000-$ 10,000 . Other minor exceptions can be found that suggest that the effect is not as universal as some of the summary combined relationships would indicate.

## MARRIAGE AGE

The expected inverse relationship between marriage age and family size appears in Table 8. S is significant and negative for all groups. It is obvious that the effect which the difference in marriage age has upon family size is more important in the lower socio-economic groups than in the higher. Similarly, differences in marriage age are somewhat more important in absolute terms for women who marry young than for those who marry later.
woman's age
As a final step in the analysis, it is possible to examine comparisons of successive woman's age levels, within pairs of other variables, to see whether on average older women tended to have larger families than

younger women. In general, Table 9 would lead to this conclusion. However, the smaller family size of women aged $40-44$ may be partly due to the fact that these families are incomplete; some children are still born to women aged $40-44$. At the next two age levels, the inverse relationship is not nearly so consistent. Thus, comparing women aged 45-49 with women aged 50-54, no significant difference in family size is found for comparisons within ( 1 ) woman's education and husband's education, (2) woman's education and husband's wages, (3) woman's education and husband's occupation, and (4) woman's education and size of community. Comparing women aged $50-54$ with women aged 55-59, there is in addition no significant difference in family size for comparisons within (5) woman's education and marriage age, (6) husband's education and husband's occupation, (7) husband's education and size of community, and (8) husband's education and marriage age. There are also other comparisons in the table which are of doubtful significance because they involve a small number of cases. By and large, however, the standardization of data for woman's education seems to have the greatest effect on the comparisons between ages, which suggests that it is changing educational levels which are responsible for much of the difference in family size for women of different ages. As was suggested earlier, the differences among women of different ages become smaller when the lower educational levels are eliminated.

## COMMENT

Pascal K. Whelpton, Director, Scripps Foundation for Research in Population Problems, Miami University
The main task which the authors undertook was to ascertain whether any one of seven chosen characteristics was independently related to the completed fertility rate of cohorts of women (the number of births per 1,000 women living to the end of the childbearing period), and, if so, the direction and strength of the relationship. I think that they developed an ingenious and useful procedure. They computed the statistical significance- $\tilde{D}$-of the difference in the mean fertility rate- $F$-of successive groups classified by a given characteristic-C-within various classes for the other characteristics. The values of D fork given characteristic are then summarized by $\tilde{\mathrm{S}}$. This procedure brings out the relationship between $F$ and $C$ at various places along a $C$ continuum. For example, it shows a strong inverse relationship between fertility and education when education is low but not when education is high within various classes for each of the other five variables studied.

Because I consider myself a demographer rather than a statistician, I shall not try to evaluate from a statistical standpoint the measures which the authors developed, but shall merely say that I think $\mathbb{S}$ is useful, but not ideal. It tells us much about the significance of the fertility differentials but not enough about their size. Perhaps we can't have everything.
I wish the authors would modify slightly their statement that "the magnitude of S is not a measure of the magnitude of the mean of the $\tilde{\mathrm{D}}$ 's." The formula they use to compute $\tilde{\mathrm{S}}$ is $\tilde{\mathrm{S}}=\frac{\sqrt{\overline{\mathcal{N}}} \Sigma \tilde{\mathrm{D}} \text {. It seems }}{\mathcal{N}}$ obvious that the magnitude of $\tilde{\mathrm{S}}$ does vary with the magnitude of the mean of the $\tilde{\text { D }}$ 's, although not proportionally because of the effect of $\sqrt{ } \overline{\mathcal{N}}$ as a multiplier in the numerator.

It may be well to point out that the usefulness of $\mathbb{S}$ depends on the size of the sampling ratio. If the data being analyzed were for the universe instead of a sample, it seems to me that S would be of little value.

The study was restricted to urban native-white women of native parentage, aged " $40-70$ " (probably $40-69$ inclusive), married once and to native born white men of native parentage. I sympathize with the reasons for the nativity and parentage restriction, namely, to rule out the influence of first and second generation immigrants on fertility trends and differentials. I am bothered, however, by the effect which it may have on the interpretation of the findings. As shown in the population breakdown the sample contained ino,ooo women meeting all the requirements except nativity and parentage but only 40,000 after the nativity and parentage restrictions were applied.

One of the results of this reduction undoubtedly is to increase substantially the proportion of women who are Protestants. This occurs because Catholics were much more numerous relatively among the immigrants arriving between 1900 and 1940 than among the population of 1900 . Another effect is to raise the proportion of women who are migrants from the southern hill areas, in which the proportion of the white population that is native born of native parentage is unusually high. It may well be that the nativity and parentage restrictions introduce other changes. Prior to 1940 there had been much intermarriage of immigrants (also of their children) on the one hand, and, on the other hand, intermarriage of the descendants of earlier generations of migrants who constituted the remainder of the white population. Consequently, the sample in question may be heavily weighted with somewhat isolated "pocket" groups.

The remainder of my comments relate in greater degree to the data that the authors used than to the use they made of these data. The information on children ever born that has been collected and published by the Bureau of the Census is very valuable; I am delighted to see it used in this and other studies. In interpreting the results, however, it may be desirable to think about the extent to which biases may be introduced because no report on births was obtained from many women (about io to 12 per cent of those in the age groups considered here). Investigations made by the Bureau of the Census indicate that the nonreporting women had borne fewer children than the others. If there is a relation between nonreporting and the characteristics being studied, this may bias the size of the observed fertility differentials. A similar statement may be made with respect to the tendency for the omission of some of the children borne by the reporting women. This and other biases probably affect the fertility differentials between successive birth cohorts.
The effect of no report for certain other items-especially husband's occupation and wages-may be more damaging. This may be illustrated by the data for women aged " $65-70$ " in Tables AI through A15. The tables relating to husband's occupation and/or wages include only 863 to $\mathrm{I}, 28 \mathrm{I}$ of the (approximately) 2,350 women aged " $65-70$ " in the sample; the birth rate of these women is between 2,229 and 2,459 . In contrast, the tables not relating to these variables contain between 2,033 and 2,316 women; their birth rate is between 2,646 and 2,883 . (The explanation probably is that a relatively large proportion of the husbands for whom occupation and/or wages are not reported are in the upper socio-economic groups where fertility is relatively low.) An unfortunate result of this bias is that 10 of the tables in question place the fertility of women aged $65-70$ below that of women aged $60-64$ while the other 5 tables place it higher. How is it possible to analyze the relation between the fertility of one group of cohorts and that of a preceding group when the data used for certain characteristics show an upward trend in fertility over time and those used for other characteristics show a downward trend?

Migration undoubtedly influences the differentials being studied here. For example, the lower socio-economic groups probably contain a relatively high proportion of migrants from the southern Appalachians, who have a high fertility background. Part of the apparent relation between fertility and the measures of economic status employed in this study may reflect the cultural differences between these migrants and the couples that had lived longer in the North Central region.

One of the important differentials shown is that between educational
groups. In considering the meaning of these differentials we need to keep in mind the increase from earlier to later cohorts in the proportion of women classified as high school graduates or as having some college education. It is probable that the rise in the relative size of these groups is associated with changes in the distribution of each group by socioeconomic and cultural background-higher education has become less restricted to the upper groups of the population.

It is most unfortunate that the influence of religion on fertility could not have been considered. Religion undoubtedly affects some of the differentials in question, for example, those relating to size of community. Evidence from other studies shows that the fertility of Catholic wives exceeds that of Protestant wives, which in turn is above that of Jewish wives. It shows also that the proportion of Catholics varies directly with size of community and that the inverse relation between fertility and size of city is larger when religion is controlled than when it is uncontrolled.

Because of the need for data for religious groups I was very happy when I heard that the Bureau of the Census had asked a question on religious preference in the Current Population Survey of March 1957, and more pleased when I saw some of the tables prepared from these data. Later I was greatly shocked to hear that the Bureau had been forbidden to publish the data which had been collected and tabulated except those in the Statistical Abstract for 1958.

In closing I would like to call attention again to the difficulty in generalizing from the results for native-white women of native parentage when information is not available about religious differentials in fertility. The authors say, "In conclusion, therefore, it would seem that as the income and education of the general population increase, the differences in family size of different groups will become smaller, and the population will become very much more homogeneous with respect to family size." In evaluating this conclusion I remember that the Indianapolis Study (in 1941) and the nationwide study Growth of American Families (in 1955) show that the differences between the fertility of Catholic and Protestant wives are greater among upper than lower educational groups. It may be, therefore, that as larger proportions of our population go to college the Protestant-Catholic differentials in fertility will increase. This would partially balance, and might more than offset, the tendencies found by the authors for other differentials to diminish in the future.
