NBER WORKING PAPER SERIES

CAPITAL MARKET INTEGRATION AND WAGES

Anusha Chari
Peter Blair Henry
Diego Sasson

ABSTRACT

For three years after the typical emerging economy opens its stock market to inflows of foreign capital, the average annual growth rate of the real wage in the manufacturing sector increases by a factor of three. No such increase occurs in a control group of countries. The temporary increase in the growth rate of the real wage drives up the level of average annual compensation for each worker in the sample by 487 US dollars—an increase equal to nearly one-fifth of their annual pre-liberalization salary. The increase in the growth rate of labor productivity in the aftermath of liberalization exceeds the increase in the growth rate of the real wage so that the increase in workers' incomes does not drive up unit labor costs. Overall, the results suggest that trade in capital may have a larger impact on wages than trade in goods.

1. Introduction

The impact of trade on wages occupies a salient space in the collective imagination of the economics profession. When a country opens up to trade with the rest of the world, income shifts away from that country's scarce factor of production and toward the one which is abundant (Stolper and Samuelson, 1941). Inspired by the celebrated Stolper-Samuelson Theorem, economics journals abound in articles examining the extent to which trade induces factor price equalization.

The evidence so far is mixed. The consensus view suggests that trade with developing countries is, at best, a modest force behind the large decline in the relative wages of low-skilled workers in rich countries (Krugman, 1995; Lawrence and Slaughter, 1993; Cline, 1997; Lawrence, 2008).[1] In the case of workers in developing countries, the evidence actually runs contrary to the theory. Whereas Stolper-Samuelson predicts that trade with rich countries will increase the relative wages of low-skilled workers in poor countries, trade liberalization during the 1980s and 1990s actually increased wage inequality in the developing world (Goldberg and Pavcnik, 2007).

Moving from trade in goods to trade in factors, an extensive literature also exists on the impact of labor flows on wage inequality. Again, the results are mixed. Some studies find that immigration from developing countries exacerbates wage inequality in the U.S. (Borjas, Freeman and Katz, 1997). Others find little to no effect (Card, 2009, Ottaviano and Peri, 2008).

While many studies examine the impact of cross-border flows of goods and workers on relative wages, the literature pays far less attention to the impact of cross-border financial flows on the absolute level of wages. This is surprising for at least three reasons.

First, trade in capital between nations has implications for real wages that are every bit as

---

[1] Feenstra and Hanson (2003) provide a dissenting view.

important as cross-border movements of goods and people. In emerging economies where capital is scarce and labor abundant, opening up to free trade in capital should reduce the rental rate and increase the real wage.

Second, examining the absolute level of wages provides information about the impact of opening up on the distribution of income between capital and labor that is just as important as the information that studies of wage inequality provide about the distribution of labor income between high and low-skilled workers. For instance, many emerging economies experienced unprecedented increases in national income as a result of globalization in the 1980s and 1990s. If all of the income gains from globalization accrued to capital, then the rise in wage inequality documented by Goldberg and Pavcnik (2007) necessarily implies that low-skilled workers experienced income losses. On the other hand, if total labor income grew in line with (or faster than) the economy as a whole, then high skilled workers may have experienced income gains that did not result in losses for low skilled workers.

Third, in the late 1980s emerging economies all over the world began easing restrictions on capital inflows of all kinds, giving economists a series of before-and-after experiments with which to study the impact of factor flows on factor rewards. A large body of research examines the impact of capital market liberalization on asset prices, investment and the growth rate of GDP per capita.[2] But to the best of our knowledge, this literature is silent about the impact of capital account opening on the labor market. Consequently, two decades after the onset of capital market liberalization, we still have no systematic evidence about the impact of this sea-change in policy on the average level of wages in the developing world.[3] This paper provides the

---

[2] See Henry (2007) and Obstfeld (2009) for comprehensive surveys of this literature.
[3] Feenstra and Hanson (1997) explore the cost of capital but focus on its impact on relative wages. Aitken, Harrison and Lipsey (1996), Almeida (2007), and Hale and Long (2008) examine FDI and wages, but not the general connection between financial flows and wages vis-à-vis the cost of capital.

first systematic attempt to fill that gap.

Figure 1 demonstrates that the level of the average annual manufacturing real wage in a sample of twenty five emerging economies increased significantly after they liberalized restrictions on inflows of foreign capital between 1986 and 1996.[4] Formal estimates show that the growth rate of the real wage in local currency terms jumped from 1.8 percent per year in the pre-liberalization period to an average of 5.7 percent in the year liberalization occurred and each of the subsequent three years. The 3.9 percentage-point increase in the growth rate of the real wage growth during this window drives up the level of average annual compensation for each worker in the sample of liberalizing countries by the local currency equivalent of 487 US dollars—an increase equal to eighteen percent of their annual pre-liberalization salary.

One concern about Figure 1 is that an exogenous world-wide shock unrelated to capital market opening may drive up real wages in liberalizing and non-liberalizing countries alike. To distinguish the country-specific impact of liberalization policy from that of a common shock, our estimation procedure compares the difference in wage growth before and after liberalization for a group of countries that open up, to the same difference for a group of control countries. Our regressions also include year fixed effects to account for the possibility of common shocks that affect only the liberalizers, and country fixed effects to allow for differences in underlying unobservable factors that may drive variation in wage growth across countries. We also control for the impact of contemporaneous macroeconomic reforms such as inflation stabilization, trade liberalization, privatization and Brady Plan debt relief programs. In every specification, we find an economically and statistically significant increase in real wage growth for countries in the liberalization group relative to the control group.

---

[4] In order to have comparable measures of levels of wages across countries, we plot the natural log of the real wage in PPP adjusted US dollar terms.

An open economy interpretation of the neoclassical growth model provides the cleanest qualitative explanation of the new facts we uncover. Opening up to capital inflows reduces the cost of capital in developing countries, and firms respond by increasing their rate of investment. For a given growth rate of the labor force and total factor productivity, a higher rate of investment increases the ratio of capital per effective worker, driving up the marginal product of labor, and in turn, the market-clearing wage. Consistent with this chain of logic, Figure 2 demonstrates that the growth rate of labor productivity also rises sharply following liberalizations. After controlling for other factors, the average growth rate of labor productivity is 9.72 percentage points higher during the four-year liberalization window than it is in non-liberalization years.

From a quantitative perspective, however, it is less clear whether the neoclassical model captures all relevant features of the data. In the standard growth model, capital account liberalization works strictly through its impact on capital accumulation and has no effect on the growth rate of aggregate total factor productivity (Gourinchas and Jeanne, 2006). The increase in real wage growth present in the data is too large to be explained exclusively by capital deepening under conventional assumptions about capital shares and the elasticity of substitution. One possible explanation stems from the observation that liberalizations increase the quantity of capital goods that emerging economies import from industrial nations (Alfaro and Hammel, 2007). If technology diffuses from developed to emerging economies through the technology embodied in capital goods imports à la Eaton and Kortum (1999, 2001a, b), then liberalizations may indeed drive up the growth rate of total factor productivity.

While our approach enables us to test previously unexamined real-wage implications of capital market opening, difference-in-difference estimation requires caution because the standard

errors are susceptible to serial correlation (Bertrand, Duflo, and Mullainaithan, 2004). Opening up to foreign capital increases investment, which in turn drives up productivity and wages. Because wages take time to adjust, wage growth for a given country may remain elevated above its steady-state rate for a number of years after opening, thereby inducing serial correlation in the country's wage-growth residuals. Similarly, many countries open up at approximately the same time, possibly inducing cross-country correlation in the residuals. Our empirical analysis uses the Petersen (2009) technique to simultaneously adjust the standard errors for the potential presence of both types of correlation in the residuals. No matter how we compute the standard errors, the impact of capital market opening on wages and productivity remains economically and statistically significant.

The potential endogeneity of the liberalization decision also raises some concerns. If profit-maximizing firms in a financially closed economy face the prospect of rapidly rising labor costs they will want to substitute capital for labor. To the extent that opening up the capital account would reduce the cost of capital, these firms have an incentive to lobby the government to do so. If rising wages cause governments to open up then our estimates will spuriously indicate a strong impact of liberalization on wages, when causation in fact runs the other way round. While theoretically plausible, the endogeneity argument has no empirical support. Figure 1 is not consistent with the view that capital market opening occurs in response to rising labor costs. If anything, wage growth actually falls slightly prior to the opening (Section 4C shows that mean reversion à la Ashenfelter (1978) does not drive our results). The data are also not consistent with the explanation that governments liberalize in anticipation of higher future labor costs. Although wages rise sharply in the aftermath of liberalization, labor productivity rises even faster, so unit labor costs do not increase.

Finally, with only twenty five countries in the sample, one may worry that a few large

outliers drive the central finding. This is not the case. Sign tests show that the median growth

rate of real wages in the post-liberalization period exceeds the pre-liberalization median too often

to be explained by chance.

The rest of the paper proceeds as follows. Section 2 uses theory to generate testable

predictions and explains how we identify real-life liberalization episodes. Section 3 describes

the data, construction of the control group, and presents preliminary findings. Section 4

discusses the empirical methodology, main results, and alternative interpretations. Section 5

examines the consistency of the results with the theory. Section 6 concludes.

2. Capital Market Integration in Emerging Economies

This section uses an open economy version of the Solow model to generate previously

untested predictions about the impact of capital flows on the time-path of the real wage (w).

The central theoretical point about capital market integration is that it moves emerging

economies from a steady state in which their ratios of capital to effective labor are lower (and

rates of return to capital higher) than in the industrialized world, towards a steady state in which

ratios of capital-to-effective labor and rates of return are equal in both regions.

Because capital and labor are complements in production, the marginal product of labor

(and hence the real wage) rises as countries open up and the process of capital deepening sets in.

This fundamental insight about capital flows and the dynamic path of wages would also hold in

an open economy Ramsey model. Since the focus of the paper is on wages, not other variables

(e.g., the current account) that depend on endogenous savings decisions, the Solow model

provides the most concise exposition.

2A. Theory

Assume that the country produces output using capital, labor, and a constant-returns-to-scale production function with labor-augmenting technological progress:

$$Y = F(K, AL) \tag{1}$$

Let $k = \dfrac{K}{AL}$ be the amount of capital per unit of effective labor and $y = \dfrac{Y}{AL}$ the amount of output per unit of effective labor. Using this notation and the homogeneity of the production function we have:

$$y = f(k) \tag{2}$$

Also assume that the country saves a constant fraction of national income each period and adds it to the capital stock, capital depreciates at the rate δ, the labor force grows at the rate n, and total factor productivity grows at the rate g.

When the economy is in steady state, k is constant at the level $k_{s.state}$, and the marginal product of capital equals the interest rate (r) plus the depreciation rate:

$$f'(k_{s.state}) = r + \delta \tag{3}$$

Because the impact of liberalization works through the cost of capital, equation (3) has important implications for the dynamics of k and w in the aftermath of opening up.

Let $r*$ denote the exogenously given world interest rate. The standard assumption in the literature is that $r*$ is less than r, because the rest of the world has more capital per unit of effective labor than the developing country. It is also standard to assume that the developing country is small, so that nothing it does affects $r*$. Under these assumptions, capital surges in to exploit the difference between $r*$ and r when the developing country liberalizes.

The absence of any frictions in the model means that the country's ratio of capital to

effective labor jumps immediately from $k_{s.state}$ to its post-liberalization, steady-state level

($k_{s.state}^*$). In the post-liberalization steady state, the marginal product of capital equals the world

interest rate plus the rate of depreciation:

$$f'\left(k_{s.state}^*\right) = r^* + \delta \qquad (4).$$

Instantaneous convergence implies that interest rates equalize immediately and that the country

installs capital at the speed of light. Two remarks about this unattractive feature of the model are

in order.

First, instantaneous capital market convergence is not an artifact of the Solow model, but

of the small open economy assumption under which liberalization gives the country access to an

infinitely elastic supply of capital at the world interest rate. The same counterfactual

phenomenon would also occur in an open economy Ramsey model. Second, although we do not

see equalization of interest rates and capital-labor ratios across countries in the real world, a large

literature documents that the cost of capital drops and investment booms when developing

countries remove barriers to capital inflows.[5]

There are a variety of formal methods for slowing down the speed of transition (e.g.,

adjustment costs of capital installation), but all of these methods would belabor the exposition

without altering the model's fundamental prediction.[6] The vital point is that $\dot{k}$ is greater than 0

during the country's transition to its post-liberalization steady-state. The temporary growth in k

has important implications for the time path of real wage growth, which we now derive.

The growth rate of the real wage is the derivative of the natural log of w with respect to

time, that is, $\dfrac{\dot{w}}{w} = \dfrac{d}{dt}(\ln w(t))$. Since workers are paid their marginal product of labor,

---

[5] See Henry (2007), Stulz (2005) and the references therein.
[6] See chapter 2 of Barro and Sala-i-Martin (1995) and Section 4.1 of Henry (2007).

$w = A[f(k) - kf'(k)]$. This means that the growth rate of the real wage is given by:

$$\frac{\dot{w}}{w} = \frac{d}{dt}(\ln(w(t))) = \frac{d}{dt}\{A[f(k) - kf'(k)]\} = \frac{\dot{A}}{A} - \frac{kf''(k)\dot{k}}{[f(k) - kf'(k)]}.$$

We may write this expression as

$$\frac{\dot{w}}{w} = \frac{\dot{A}}{A} + \frac{1}{\sigma} * \frac{f'(k)k}{f(k)} * \frac{\dot{k}}{k} \qquad (5)$$

where $\sigma = -\dfrac{f'(k)[f(k) - kf'(k)]}{f(k)f''(k)k}$ is the elasticity of substitution.

The right-hand-side of Equation (5) demonstrates that the growth rate of the real wage depends on the sum of two terms. The first term, the growth rate of total factor productivity $(\frac{\dot{A}}{A})$, is not affected by capital account policy in the canonical version of the neoclassical growth model. In Section 5 we discuss the implications of recent work that adopts a more catholic view of the relationship between capital account liberalization and total factor productivity. For now, we proceed as though the impact of liberalization works strictly through the second term, which is the product of the inverse of the elasticity of substitution $(\frac{1}{\sigma})$, capital's share in national income $(\frac{f'(k)k}{f(k)})$, and the growth rate of the ratio of capital per unit of effective labor $(\frac{\dot{k}}{k})$.

Prior to liberalization, the ratio of capital to effective labor is constant at the level $k_{s.state}$, so that $\frac{\dot{k}}{k}$ equals 0, and w simply grows at the same rate as total factor productivity. Since $\frac{\dot{k}}{k}$ is greater than 0 during the transition to $k^*_{s.state}$, the growth rate of the real wage also increases

9

temporarily. Figure 3 illustrates the hypothetical time paths of *r* and the natural logs of *k* and *w* under the assumption that the interest rate converges immediately upon liberalization but the ratio of capital to effective labor does not.

Again, previous work documents that the actual responses of the cost of capital and the quantity of capital to liberalization resemble their hypothetical time paths. Figure 1 demonstrates that the growth rate of the real wage also behaves in accordance with the theory. In Section 5 we examine whether the size of the real wage increase is consistent with the magnitude of the previously documented increases in the growth rate of capital. The next subsection explains how we identify the real-life liberalization episodes used to construct Figure 1.

2B. Reality

An ideal test of the prediction that real wage growth will rise following the removal of restrictions on capital inflows requires information on capital account liberalization dates that is more precise than one can generally obtain. In theory, opening the capital account is as simple as pulling a single lever. In reality, the capital account has many components, so trying to determine exactly when a country liberalizes (as in Section 2A) is not a trivial task. In fact, the difficulty of determining precise liberalization dates causes most papers in the literature to ignore the problem (Eichengreen, 2001). Instead of asking whether *opening* the capital account has an impact on a country's growth rate (as theory clearly dictates), most published studies examine whether *openness* and long-run growth are positively correlated across countries. A brief description of the data typically employed in such studies illustrates why tests of *opening* and *openness* are not equivalent.

To construct measures of openness, previously published work uses the broadest

indicator of capital account policy available, the IMF's *Annual Report on Exchange Arrangements and Exchange Restrictions* (AREAER). The AREAER lists the rules and regulations governing resident and nonresident capital-account transactions in each country, a table summarizing the presence of restrictions, and a qualitative judgment on whether the country has an open or closed capital account. For the editions of AREAER published between 1967 and 1996, the summary table contains a single line (line E2) entitled, "Restrictions on payments for capital transactions." The presence of a bullet point in line E2 indicates that the country has some form of restrictions on capital account transactions. In effect, line E2 delivers a binary judgment on whether the IMF considers a country's capital account to be open or closed.

The typical study maps the qualitative information from Line E2 into a quantitative measure of openness by tallying the number of years that each country was free from restrictions. Dividing that tally by the total number of years in the period produces a number called *SHARE*— the fraction of years over a given period that the IMF judged the country as open. For example, if a country was declared open for 15 of the 30 years from 1967 to 1996, then *SHARE* equals 0.5.

Papers that use the variable *SHARE* assess the economic impact of capital account policy by running cross-country regressions of GDP growth on *SHARE*. The problem with cross-sectional regressions of growth on SHARE is that they have little statistical power to distinguish the transitional impact of liberalization on growth from the noise in the data and can easily generate spurious conclusions (see Henry, 2007, p, 893). The cross-sectional regression approach is equally ineffectual for estimating the impact of liberalization on the growth rate of wages. Because theory predicts a short-lived impact of liberalization on the growth rate of wages, it is not enough to know the fraction of years in which a country had an open capital

account. We need to know the exact year in which the country began opening.

In principle, one could look for the year in which the judgment in line E2 of the AREAER switches from "closed" to "open." The problem is that when the AREAER changes its assessment of a country from closed to open, it does not indicate whether the change in judgment results from an easing of restrictions on capital inflows or outflows. The distinction matters. Theory predicts that when a capital-poor country liberalizes restrictions on capital inflows it will experience a permanent fall in its cost of capital and a temporary increase in the growth rate of wages. In principle, if that same country were to liberalize capital outflows nothing would happen to its cost of capital, investment, or GDP.[7]

In contrast to the previous literature which makes no attempt to find periods of opening, this paper identifies liberalization dates using the point in time when countries first permitted foreigners to purchase shares of companies listed on the domestic stock market. Relative to the most general conception of the capital account, at first blush the lifting of restrictions on foreign investment in the stock market may seem like a narrow way to define capital account liberalization. But deeper reflection reveals that stock market liberalizations serve as observable *de facto* indicators of harder-to-pinpoint *de jure* policy changes.[8]

For instance, the opening of a country mutual fund is the modal means through which countries first liberalize the stock market (see Table 1). If country-fund-opening dates are valid proxies for the occurrence of broader, undocumented liberalizations that took place in the late 1980s and early 1990s, then significant quantities of capital that are not associated with any particular country fund may flow in to the country as a consequence of the opening. Three facts suggest that our stock market liberalization dates provide non-specious indicators of a larger

---

[7] For discussions of why this may not occur in practice, see Alfaro, Kalemli-Ozcan, and Volosovych (2008) and Shleifer and Wolfenzon (2002).
[8] See Kose et al. (2006) for a detailed discussion of de facto versus de jure indicators.

move towards open capital markets.

First, a steady stream of country funds, issuances of American Depository Receipts, and other vehicles for foreign savers to buy domestic stocks typically follow the initial stock market liberalizations (Karolyi, 2004; Gozzi, Levine and Schmukler, 2010). As a case in point, Chile liberalized its stock market in May 1987 through the *Toronto Trust Mutual Fund*, a Canadian closed-end fund with a net asset value of 37.7 million US dollars.[9] In the next five years, six additional country funds with a cumulative net asset value of 991.8 million dollars were established in Chile.[10]

Moving beyond Chile, Figure 4 demonstrates the extraordinary change wrought by stock market liberalizations in emerging economies. Net inflows of equity capital to the developing world, practically non-existent in the 1970s and early 1980s, accelerated sharply after the median stock market liberalization date in our sample (1989). Policy makers often raise concerns about the potential volatility of portfolio capital, worrying that net inflows of equity can easily turn to net outflows at the first sign of trouble. The facts do not substantiate this concern. While Figure 4 indicates that the pace of equity inflows to developing countries slowed following the Mexican Crisis in 1994-95 and the Asian Crisis of 1997-98, there is nothing that remotely resembles a reversal of equity inflows.[11]

It is also important to note that stock market liberalizations account for a substantial fraction of foreign direct investment (FDI), the most stable form of foreign capital. A common misconception views FDI solely as green field investment where a foreign company builds from scratch a new manufacturing plant in an emerging economy. As a matter of official statistics,

---

[9] See Park and Van Agtmael (1993), Price (1994), and Wilson (1992).
[10] See Park and Van Agtmael (1993), Price (1994), and Wilson (1992).
[11] Concerns about the volatility of debt flows, on the other hand, are quite well founded. See Henry (2007) and Rogoff (1999).

FDI includes any stock transaction (i.e., a cross-border merger or acquisition) that results in the purchaser owning 10 percent or more of the voting shares.[12] In fact, from 1991-2000, cross-border mergers and acquisitions accounted for 48 percent of FDI in Latin America and 61 percent in East Asia (Chari, Ouimet, and Tesar, 2004).

Second, the facilitation of cross-border financial flows and ownership through stock market liberalization also induces large flows of physical capital. Stock market liberalizations in emerging economies coincide with a significant increase in their imports of capital goods. In a sample of twenty-five countries that liberalized their stock markets between 1980 and 1997, liberalization leads to a 9-percent increase in capital goods as a fraction of total imports, and the share of total machine imports to GDP rises by 13 percent (Alfaro and Hammel, 2007). Because developing countries do not produce a significant portion of the capital goods that they use, the observation that imports of capital goods rise in concert with the advent of portfolio equity inflows increases confidence in earlier work on liberalization and aggregate investment.

Third, with the sole exception of Malaysia during the Asian Crisis, none of the stock market liberalization dates from Table 1 were followed by a reversal of freedom of foreign access.

Taken together, these three facts confirm that stock market liberalizations signify the beginning of a steady march toward greater freedom of capital inflows and provide the closest empirical analogue to the textbook example in Section 2A. Accordingly, we use the stock market liberalization dates in Table 1 as the empirical counterpart to year "0" in the model of Section 2A (Figure 3). Standard and Poor's Emerging Markets Database covers 53 emerging

---

[12] The Organization of Economic Cooperation and Development (OECD) defines foreign direct investment (FDI) as: "A category of cross-border investment made by a resident in one economy (the *direct investor*) with the objective of establishing a lasting interest in an enterprise (the *direct investment enterprise*) that is resident in an economy other than that of the direct investor. The "lasting interest" is evidenced when the direct investor owns at least 10% of the voting power of the direct investment enterprise" (OECD, 2008).

economies with stock markets. Of these 53 countries, 25 have stock market liberalization dates that are: (a) consistently used elsewhere in the literature and (b) verifiable from primary sources. Column (1) of Table 1 lists these twenty five countries and the year in which they liberalized.[13] Table 2 presents summary statistics on the behavior of real wages in each of the twenty five liberalizing countries. The next section explains the source and construction of the wage data.

3. Data

The wage data come from the Industrial Statistics Database of the United Nations Industrial Development Organization (UNIDO). UNIDO provides data on total wages and salaries, total employment and output for the manufacturing sector. For a given year, wages and salaries include all payments to employees in cash or in kind. Payments include: (a) direct wages and salaries; (b) remuneration for time not worked; (c) bonuses and gratuities; (d) housing allowances and family allowances paid directly by the employer; and (e) payments in kind. Excluded from wages and salaries are employers' contributions on behalf of their employees to social security, pension and insurance schemes, as well as the benefits received by employees under these schemes and severance and termination pay.

Conceptually, total wages and salaries equal $W*L*H$, where W is the hourly wage rate, L is the stock of labor and H is total hours worked for the year. Since UNIDO provides no data on the number of hours worked or the hourly wage, we divide total wages and salaries by total employment (L) to compute the average annual wage ($W*H$) of each worker in the manufacturing sector of each country (more on this point in Section 3B.1). UNIDO reports the value of wages and salaries in local currency terms. We deflate each country's nominal annual wage in local currency by the local consumer price index (CPI) to create a local currency-

---

[13] For further details about the complexities of determining liberalization dates see Section 5 of Henry (2007).

denominated real wage.

In addition to information on wages, employment, and output, we would like to have data on the manufacturing capital stock. Unfortunately, UNIDO only provides data on investment. The standard approach to an absence of capital stock data converts investment flows to capital stocks with the perpetual inventory method by making assumptions about the initial level of capital in some year and using the investment flows to interpolate the subsequent time path of the capital stock.

Interpolation is methodologically sound when the focus is on long-run relationships where assumptions about the initial stock of capital make little difference. In contrast, this paper focuses on short-run dynamics and therefore requires a clear picture of the trajectory of the capital stock during the liberalization window. Simply put, it would be inappropriate to interpolate the growth rate of the capital stock during liberalization episodes when trying to measure the impact of liberalization on capital stock growth. Moreover, the UNIDO data set is missing more than 50 percent of the country-year observations for investment in the aggregate manufacturing sector, and many of these missing observations fall within the liberalization window. In the absence of reliable capital stock data, we will use (in Section 5) estimates of capital stock growth from previously published work to check the consistency of our results with the theoretical channel from capital growth to wages.

For each country in our sample, the annual wage data generally run from 1960 to 2003, with the exact dates differing by countries. After taking the difference of the natural log to compute growth rates, we have a total of 758 country-year observations with which to identify the impact of liberalization on real wage growth. Table 1 shows that the timing of liberalizations is correlated across countries, so these 758 observations are not independent. For instance,

liberalizations may coincide with an exogenous global productivity shock that drives up wages in all countries, irrespective of whether or not they liberalize.

To address whether it is the case that an exogenous shock unrelated to opening up drives the temporary increase in real wage growth, we select a group of control countries. The control group consists of developing countries that are similar to the liberalizing countries except that the control countries did not open their stock markets to foreign investment. Appendix A provides a list of countries that have stock markets but never liberalized. These nations comprise the control group against which we compare the real wage growth of the countries in our treatment group.

3B. Descriptive Findings and Data Concerns

Figure 1 exhibits a steep positive inflection after year [0], indicating a sharp increase in the growth rate of the real wage. However, with only twenty five countries in the sample an important question is whether a few outliers drive the increase.

The descriptive statistics in Table 2 suggest that this is not the case. Only four countries—Indonesia, Malaysia, Pakistan, and Thailand—have mean growth rates in the aftermath of liberalization that do not exceed their full sample mean (column 2). Turning from means to medians, for each country in the sample we also performed simple Wilcoxon sign rank tests on the data for each country (Wilcoxon, 1945). The procedure tests the equality of matched pairs of observations by using the Wilcoxon matched-pairs signed-ranks test. Applied to the current context, the null hypothesis is that the distributions of pre- and post-liberalization wage growth are the same. In the three-year post-liberalization period, five countries experience median real wage growth that falls below the median growth rate of their real wage in the pre-liberalization period. Given the null hypothesis, the probability (p-value) of finding no more

than five countries with wage growth rates below their pre-liberalization median is 0.0015.

Table 2 (Panel A) also shows the following quantities: (a) for each country, Column 1 gives the change in the natural log of the wage over the liberalization window (years [0] to [3]); we denote this variable "liberalization log wage change" as a convenient shorthand expression; (b) Column 2 gives the liberalization log wage change for each country expressed relative to the country's mean log wage change over the pre-liberalization window (years [-3] to [-1]); (c) Column 3 gives the liberalization log wage change for each country expressed relative to the contemporaneous mean log wage change for the control group over the liberalization window (years [0] to [3]); (d) Column 4 gives the "difference-in-difference" that results from subtracting the real log wage change for the treatment countries expressed relative to the control group in the pre-liberalization window from the quantity in Column 3.

The average cumulative log wage change for the treatment group during the liberalization window is 15.8% (Column 1); Relative to the pre-liberalization window, the cumulative log wage change is 19.1% (Column 2). Relative to the control group during the liberalization window, the cumulative log wage change is 26% (column 3). The average difference-in-difference of the cumulative log wage change is 20.2% (column 4).

For each of the quantities in Columns 1-4, we test whether the mean differs significantly from zero and report a heteroscedasticity-consistent estimate of the standard error in Table 2, Panel B. These simple tests support the observation that liberalization leads to large effects on the level of real wages, lending credence to the more sophisticated regression results that follow.

To provide additional descriptive evidence, Table 3 presents estimates of the impact of liberalization on the growth rate of real wages over time. Panel A of Table 3 presents estimates of one coefficient only, but allowing progressively more periods after the reform (from year 2 up

to 5). For example, the coefficient on *DUMMY03* estimates the average effect of liberalization on real wage growth in years [0], [1], [2], and [3]. The coefficient estimate of 0.0369 suggests that the average real wage growth in that four-year span is 3.69% per year, or an overall increase of 14.76 percentage points (3.69*4). The average estimated effect of liberalization on wage growth differs between specifications. Consistent with the theoretical prediction that liberalization will produce a temporary increase in wage growth, the average effect becomes progressively smaller as we add more years subsequent to the liberalization window. We also estimated the coefficient estimates on the liberalization dummy over the [0, 2], [2, 4], and [4, 6] event windows. However, the interpretation of the statistical difference of the coefficients across the different windows is difficult given their overlapping nature.

Panel A also presents an estimate of the "Ashenfelter" dip. The variable "Dummy ([-3], [-1])," which takes on a value of one for the three years before liberalization, shows that the pre-reform dip in wage growth (2.37%) is smaller and less significant than the post-reform average real wage growth of 3.69% in the four years following liberalization.

Panel B presents the coefficient estimates on the liberalization dummy by individual year, ranging from the liberalization year [0] up to five years following the liberalization [5]. Columns 2 and 3 indicate that the impact of liberalization on real wages is positive and significant in both the first [1] and second [2] years following the liberalization. The coefficient estimates on the liberalization dummy are not significant in years [3] to [5]. The estimates in years [1] and [2] are significantly different from the coefficients in the other years.

Although the numbers in Tables 2 and 3 suggest a reasonably consistent increase in real wage growth across countries, two other questions about the data remain.

3B.1 Hours Worked

First, the necessity of using annual data instead of hourly wages raises a potential measurement concern. If the average number of annual hours worked per employee increases following liberalizations, then total annual compensation may rise without any change in the implied hourly wage. In other words, the rise in average annual labor income ($W*H$) documented in Figure 1 could be the result of an increase in hours worked rather than an increase in the hourly wage rate. To interpret the impact of liberalization on total annual compensation as an increase in labor's compensation per unit of time, we need to know that the average number of hours worked does not rise significantly following liberalizations.

In an attempt to address this concern we ran into non-trivial constraints that forced us to rely on data for a subset of the countries in our sample. UNIDO does not provide information on hours worked. Data available from the International Labor Organization (ILO) is also not helpful because the ILO's definition of hours worked is inconsistent across countries. Within a given country, the ILO's definition of hours worked sometimes varies across sectors and over time as well. In the end, we used data provided by the Groningen Growth and Development Center (GGDC) because GGDC seemed to take most seriously the problems associated with trying to construct a consistent cross-country measure of hours worked. In their own words, the GGDC's estimates of hours worked are based on "…a country-by-country…judgment of which sources made the most appropriate adjustments to achieve the preferred concept of actual hours worked per person employed" (GGDC, 2011). The GGDC data include paid overtime and exclude paid hours that are not worked due to sickness, vacation and holidays.

Specifically, the data on hours worked come from GGDC's Total Economy Database, which extends the work of Angus Maddison (1980). Although the Total Economy Database

contains annual numbers on GDP, population, employment, hours and productivity for about 125

countries from 1950 to 2008, the series on hours worked per person are available for only 43

countries. Twelve of those 43 countries are also in our dataset: Argentina, Brazil, Chile,

Colombia, Greece, Korea, Mexico, Portugal, Spain, Turkey, Taiwan, and Venezuela.

To assess whether the rise in average annual compensation is driven by an increase in

hours worked, Figure 5, which plots the natural log of hours worked in liberalization time,

illustrates that hours worked are invariant to liberalization. Between years [-5] and [-1] the

average natural log of hours worked is 7.64. In years [1] through [5] the average is 7.62. In

levels these numbers translate to an average of 2094 hours worked per year prior to liberalization

and 2066 hours worked per year after. Dividing 2094 and 2066 by the number of weeks in a

year (52, not adjusting for vacation time) gives an estimate of roughly 40 hours to the average

work week in these twelve countries before and after opening up. That number seems entirely

reasonable and reinforces our confidence in the GGDC data. Looking at medians instead of

means does not alter the story. The median natural log of hours worked before liberalization is

7.59. The median after liberalization is also 7.59. In short, the number of hours worked per year

does not change with liberalization and does not drive the increase in real wage growth

documented in Figure 1.[14]

3B.2 Concurrent Economic Events

A second concern is that capital market openings may coincide with major economic

events that could have a significant impact on wages independently of any effects of

---

[14] As a final check we also used the GGDC data to construct a measure of hourly wages for the subset of twelve
countries. Regressing the change in the natural log of the hourly wage on the same right-hand-side variables that
appear in Equation (6), we find results that are qualitatively identical to those reported in Panel A of Tables 4
through 6.

liberalization. Union activity provides a case in point. If agitation for higher pay by organized labor coincides with liberalization then the estimates may be overstated. A survey of labor market events during capital account liberalization episodes revealed that significant union activity to secure higher wages was present in only three of the twenty five countries in our sample—Brazil, Turkey and South Korea. When these countries are dropped, the cumulative raw "difference-in-difference" estimate is not substantively different at 17.39%. Also, when we control for unionization in the formal regression analysis the coefficient on the capital account liberalization dummy remains unchanged. In two other countries—Chile and South Africa—the government thwarted protestors demanding wage hikes. The other 20 countries in the sample did not experience any significant union activity during their liberalization episodes.

While union activity does not drive the increase in wages, a separate concern is that liberalizations often coincide with major economic reforms that could have a significant impact on wages apart from any effects of liberalization. Stabilizing inflation, removing trade restrictions, and privatizing state-owned enterprises are all reforms that may affect real wages through their impact on the efficiency of domestic production. Indeed, Table 1 demonstrates that the timing of these reforms makes it plausible that they, not capital account liberalization, are responsible for the increase in real wages apparent in Figure 1. The next section, which presents our formal empirical methodology and results, uses the information in Table 1 to control directly for the impact of other reforms and to address a host of lingering concerns and alternative explanations.

4. Empirical Methodology and Results

We evaluate the statistical significance of the temporary increase in wage growth by estimating the following difference in difference panel regression specification:

$$\Delta \ln w_{it}^{dif} = a_0 + COUNTRY_i + a_1 * LIBERALIZE_{it} + a_2 * TRADE_{it} + a_3 * STABILIZE_{it} \\ + a_4 * PRIVATIZE_{it} + a_5 * BRADY_{it} + \varepsilon_{it} \tag{6}$$

The left-hand-side variable, $\Delta \ln w_{it}^{dif}$, is the change in the natural log of the real local currency value of annual compensation for country i in year t minus the average change in the natural log of the real wage for the group of control countries in year t. Moving to the right-hand-side of equation (6), the variable $LIBERALIZE_{it}$ is a dummy variable that takes on a value of one in the year that country i liberalizes ([0]) and each of the subsequent three years ([1], [2] and [3]). This means that the coefficient a_1 measures the average annual deviation of the growth rate of the real wage in the treatment group from the growth rate of the real wage in the control group during the three-year liberalization episode.

The right-hand-side of equation (6) also contains four additional country-specific dummy variables—*STABILIZE*, *TRADE*, *PRIVATIZE* and *BRADY*—that are designed to prevent country-specific shocks in the shape of economic reforms from artificially inflating the coefficient on *LIBERALIZE*. We treat reforms and liberalization symmetrically, constructing dummy variables that take on the value one in the year a reform program begins and each of the three subsequent years.

Turning at last to the error term, ε_{it}, it is important to note that when the residuals are correlated across observations, OLS standard errors can be biased and may over or underestimate the true variability of the coefficient estimates. Specifically, the standard distributional assumptions needed for valid statistical inference will not hold in the presence of: (a) correlation of the

23

residuals across countries within a given time period (cross-sectional dependence), or (b)

correlation of the residuals within a given country over time (time-series dependence). Point (a)

matters because liberalizations often occur at the same time for different countries, possibly

inducing correlation in the wage-growth residuals across countries at a given point in time. Point

(b) matters because it takes time for wages to adjust to their new trajectory; for a given country,

wage growth may remain elevated above its steady-state rate for a number of years in the post-

liberalization period, thereby inducing serial correlation in the country's wage-growth residuals.

To compute accurate standard errors we employ various clustering procedures described below.

4A. Benchmark Estimates: A Difference in Difference Specification

Table 4 (Panel A) presents the results from our estimate of Equation (6), restricting the

sample to data three years before the liberalization and three years after. The standard errors are

clustered by year to account for potential cross-country correlation in the wage growth residuals.

The estimate of the coefficient on *LIBERALIZE* ranges from 0.031 to 0.043. Relative to the

control group, the average growth rate of the typical country's real wage exceeds its long-run

mean by 3.1 to 4.3 percentage points per year during liberalization episodes. The estimate of the

coefficient on the liberalization dummy in Panel A of Table 4 is statistically significant at the 1

percent level in nearly every specification.

Panel B of Table 4 estimates equation (6) using data that spans the entire sample to show

that the impact of liberalization on real wage growth is robust to potential concerns about the

length of the pre-liberalization window used for estimation. The coefficient on *LIBERALIZE*

ranges from 0.036 to 0.047 and is significant at the 1 percent level in all but one specification.

That specification is significant at the 5% level.

Controlling for the other economic reforms that tend to accompany liberalization also does not reduce the impact of capital account opening on the growth rate of the real wage. Column (6) in Panel A of Table 4 shows that after accounting for the effects of inflation stabilization, trade liberalization, and privatization, the coefficient on *LIBERALIZE* is 0.031. The impact of other economic reforms on the growth rate of the real wage is not as robust of that of liberalization, but we do find some significant effects of inflation stabilization and privatization. This reinforces our confidence in the accuracy of the reform dates and the relevance of the corresponding dummy variables as controls.

Turning from economic reforms to statistical issues, researchers do not always know whether the precise form of the dependence in residuals is time-series or cross-sectional in nature. As a way of addressing this concern, Peterson (2009) suggests a less parametric estimation approach that clusters on two dimensions simultaneously (e.g., country and time). Peterson's approach uses the following estimate of the variance-covariance matrix, which combines the standard errors clustered by country with the standard errors clustered by time:

$$V_{Country \& Time} = V_{Country} + V_{Time} - V_{White} .^{15}$$

The first matrix on the right-hand-side allows standard errors to be clustered by country, capturing the unspecified correlation between observations on the same country in different years (e.g., correlations between ε_{it} and ε_{is}). The second matrix on the right-hand-side, allows standard errors to be clustered by time, capturing the unspecified correlation between observations on different countries in the same year (e.g., correlations between ε_{it} and ε_{kt}). Since both the country- and time-clustered variance-covariance matrix include the diagonal of the variance-covariance matrix, the Peterson procedure subtracts off the White variance-covariance matrix to

---

[15] Proposed by Cameron, Gelbach, and Miller (2006), and Thompson (2006).

avoid double counting. This method allows for both a country and a time effect, although observations on different countries in different years are assumed to be uncorrelated. Peterson (2009) demonstrates through simulation that clustering by two dimensions produces less biased standard errors.

Table 5 (Panel A) presents estimates of equation (6) that use Petersen's (2009) procedure to simultaneously cluster the standard errors by year (to adjust for cross-country correlation) and by country (to adjust for serial correlation).[16] Since it is not possible to include country fixed effects while simultaneously clustering the standard errors by year and country, the magnitude of the estimates in Table 5 are not identical to those in Table 4, but they are very similar. Focusing, then, on the precision of the estimates, we see that the estimate of every coefficient in Table 5 in both Panels A and B is significant at the one percent confidence level. This suggests that our general finding is robust to concerns about both serial and cross-country correlation in the error terms.

4A.1 An Alternative Specification: Country and Year Fixed Effects

As an alternative to our difference-in-difference estimates, we regress the change in the natural log of the real wage or a full set of country-fixed and year-fixed effects plus the reform dummies. Specifically, we estimate:

$$\Delta \ln w_{it} = a_0 + COUNTRY_i + YEAR_t + a_1 * LIBERALIZE_{it} + a_2 * TRADE_{it} +$$
$$a_3 * STABILIZE_{it} + a_4 * PRIVATIZE_{it} + a_5 * BRADY_{it} + \varepsilon_{it}$$
$$(7).$$

The left-hand-side variable, $\Delta \ln w_{it}$, is the natural log of the real local currency value of annual compensation for country i in the treatment group in year t minus the same variable in

---

[16] For another discussion of multi-way clustering see Cameron, Gelbach, and Miller (2009).

year *t-1*. The variable $YEAR_t$ is shorthand for the set of year-fixed effects. The right-hand-side

of equation (7) also contains four additional dummy variables—*STABILIZE*, *TRADE*,

PRIVATIZE and *BRADY*. The standard errors are clustered by year.

Table 6 (Panel A) presents the results from our estimate of Equation (7). The standard

errors are clustered by year to account for potential cross-country correlation in the wage growth

residuals. The impact of liberalization on real wage growth is economically large. The estimate

of the coefficient on *LIBERALIZE* ranges from 0.038 to 0.043. This means that during

liberalization episodes the average growth rate of the typical country's real wage exceeds its

long-run mean by 3.8 to 4.3 percentage points per year. All but one estimate of the coefficient

on the liberalization dummy in Panel A of Table 6 is statistically significant at the 1 percent

level. Controlling for the other economic reforms that tend to accompany liberalization also

does not reduce the impact of capital account opening on the growth rate of the real wage.

Column (5) in Panel A of Table 6 shows that after accounting for the effects of inflation

stabilization, trade liberalization, and privatization, the coefficient on *LIBERALIZE* is 0.0388.

4B. Alternative Explanations

One interpretation of the evidence says that wages rise following liberalizations because

of an increase in labor demand stemming from a capital-deepening induced rise in productivity.

Alternatively, the increase in wages may be due to a reduction in labor supply. The argument

runs as follows. If workers perceive the impact of liberalization on wages to be permanent, then

they effectively receive a positive shock to their permanent income and may reduce their labor

supply accordingly. If this is the case then the observed increase in wage growth may stem from

a decrease in labor supply as well as an increase in labor demand.[17]

The employment data are not consistent with a decrease in labor supply. There is no discernible change in the growth rate of employment following liberalizations. The regression specifications in Table 8 examine the change in the natural log of employment on the same right-hand-side variables that appear in Equation (7). The liberalization dummy is never significant. Also, if labor supply decreases then we would also expect a decline in the number of hours worked. Again, Figure 4 demonstrates that this is not the case. Overall, the evidence does not suggest that workers reduce their labor supply in response to liberalization. While we do not formally estimate the labor supply decision and cannot exclude the possibility that part of the wage increase results from a decrease in labor supply, if this alternative explanation is at work its overall impact appears to be second order.

4C. Economic Interpretation

There are two ways to examine the economic significance of the results. First, consider the magnitude of the growth rate of the real wage during liberalization episodes relative to the growth rate of the real wage over the entire sample. To do this, use the estimate of the constant and the liberalization dummy from the regression that controls for other economic reforms (Column 5 in Table 6). Real wage grow by an average of 1.8 percent per year over the entire pre-liberalization sample. The estimate of the coefficient on the liberalization dummy is 0.039. Adding the average pre-liberalization real wage growth to the coefficient on the liberalization dummy gives the average growth rate of the real wage during liberalization episodes—5.7 percent per year. This means that in the year the liberalization occurs and each of the subsequent

---

[17] An alternative view is that labor supply is relatively inelastic (see Pencavel 1986 on this point). If this is the case, workers may not reduce the number of hours that they want to work in response to the increase in their expected future income.

three, the average growth rate of the real wage is almost three times as large as in non-liberalization years (5.7 versus 1.8).

Of course, the increase in the growth rate of the real wage is temporary, so a second way of assessing economic significance is to compute the impact of liberalization on the permanent level of the real wage. For the countries in the treatment group, the average level of annual compensation in the year before liberalization (year [-1]) is 2,686 PPP-adjusted dollars. During the three-year liberalization window the real wage grows at 5.7 percent per year, so that by the end of year [3] the average level of the real wage is $2686e^{0.057*4}$ = 3,374 PPP-adjusted dollars. Now assume that that in the absence of liberalization the real wage would have grown at the sample mean of 1.8 percent per year. In that case, the level of the real wage at the end of year [3] would be $2686 \, e^{0.018*4}$ = 2,887 PPP-adjusted dollars. In other words, by the time the impact of liberalization has run its course, the average worker in the manufacturing sector has annual take home pay that is 487 dollars higher (3,374 minus 2,887) than it would have been in the absence of liberalization. This change in the level of the wage is equal to nearly one-fifth of the average manufacturing worker's pre-liberalization, PPP-adjusted take home pay.

It is also important to note that the results are not an artifact of mean reversion following a temporary fall in earnings à la Ashenfelter (1978). Figure 1 shows a decline in the level of the real wage from an average of 2,968 PPP-adjusted dollars five years prior to liberalization to an average of 2,686 PPP-adjusted dollars a year prior to liberalization. A few hypothetical calculations demonstrate that the results do not simply reflect a bounce-back effect. Suppose that instead of declining, on average, for the next four years (as they do in the data), real wages grew at their (continuously compounded) long-run rate of 1.8 percent per year over the pre-liberalization window. Under that scenario, the real wage in year [3] would have been 3,485

PPP-adjusted dollars. The actual level of the average real wage in year [3] is 4,050 PPP-adjusted dollars, roughly 20 percent higher than the level that would have prevailed had wages simply continued to grow at their long-run rate.

4D. The Impact of Liberalization on Productivity

The results suggest that the response of wages to capital account liberalization is large. To scrutinize the plausibility of our estimates we cross-checked the results against data on labor productivity. The model in Section 2 demonstrates that liberalization induces capital deepening, and through the increase in capital per worker, drives up productivity, the demand for labor, and the real wage. If this chain of reasoning has any empirical bite then during liberalization episodes labor productivity should rise in concert with wages.

To formally test the relation between liberalization and the growth rate of labor productivity, we estimate the following difference in difference regression:

$$\Delta \ln(\frac{Y}{L})_{it}^{dif} = a_0 + COUNTRY_i + a_1 * LIBERALIZE_{it} + a_2 * TRADE_{it} + a_3 * STABILIZE_{it}$$
$$+ a_4 * PRIVATIZE_{it} + a_5 * BRADY_{it} + \varepsilon_{it}$$

(8).

Equation (8) is identical to (6) except that instead of the change in the natural log of the annual wage, the left-hand-side variable is now the change in the natural log of the annual real value-added per worker in local currency terms minus the average change in the natural log of real value-added per worker in the control group. Again, to be consistent with the wage estimates we cluster the standard errors by year.

Table 7 (Panel A) shows that liberalization has a positive and significant impact on productivity growth. The estimates of the coefficient on the liberalization dummy range from 0.076 to 0.097. Every estimate of the coefficient on the liberalization dummy in Panel A of

Table 7 is statistically significant. Taken together, these results suggest that liberalization, not an external shock or domestic economic reforms, is responsible for the increase in productivity growth.

In particular, Column (6) of Panel A in Table 7 demonstrates that after accounting for the potential impact of other economic reforms, the estimate of the coefficient on the liberalization dummy is 0.972. This means that the average growth rate of productivity is 9.72 percentage points higher during the three-year liberalization window than in non-liberalization years. The 9.72 percentage point increase in productivity growth associated with liberalization is larger than the 3.9 percentage point increase in wage growth. Because the increase in productivity outstrips the increase in wage growth, manufacturing-sector profitability actually rises during liberalizations.[18]

Panel B of Table 7 shows that the results for productivity growth and liberalization are robust to all of the statistical concerns raised about the estimation of wage growth and liberalization examined in Sections 4A.

5. Discussion

While the size of the increase in productivity growth more than matches the size of the increase in real wage growth, the important unanswered question is whether the magnitude of either increase is consistent with the model that drives the estimates. To answer the question, begin with the standard assumption that liberalization has no impact on TFP growth and recall

Equation (5): $\dfrac{\dot{w}}{w} = \dfrac{\dot{A}}{A} + \dfrac{1}{\sigma} * \dfrac{f'(k)k}{k} * \dfrac{\dot{k}}{k}$. With no change in the growth rate of TFP, Equation (5) implies that the change in the growth rate of the real wage equals the product of three numbers:

---

[18] Chari and Henry (2008) also find that the return to capital in the manufacturing sector rises during liberalizations.

the reciprocal of the elasticity of substitution, capital's share in national income, and the change in the growth rate of capital per effective worker.

Specifically, we have:

$$\frac{\dot{w}}{w} = \frac{1}{\sigma} * \frac{f'(k)k}{k} * \frac{\dot{k}}{k} \tag{9}$$

The capital share typically lie between 1/3 and 1/2.[19] Obtaining an estimate of the change in capital growth requires a little more effort. We know from previous work that aggregate capital stock growth increases by 1.1 percentage points following liberalizations (Henry, 2003). We can use the aggregate number to calculate a rough upper bound for the change in manufacturing sector capital growth. For the countries in our sample, the manufacturing sector accounts for about 1/5 of GDP. Assuming zero net growth in capital for the agriculture and service sectors, the largest possible increase in the growth rate of capital in manufacturing is about 5.5 percentage points. This back-of-the-envelope calculation finds empirical support elsewhere in the literature. Using a subset of the countries in this paper, Chari and Henry (2008) calculate that the growth rate of capital in the manufacturing sector increases by 4.1 percentage points per year following liberalizations. Increases in capital stock growth between 4.1 and 5.5 percentage points are also consistent with the size of the fall in the cost of capital that occurs following liberalizations.[20]

Suppose the capital share is 1/2 and the change in capital growth is 5.5 percentage points. Then for capital-deepening alone to explain the 3.9-percentage-point increase in wage growth you need an elasticity of substitution less than or equal to 0.7. If the capital share is 1/3 and the change in capital growth is 4.1 percentage points, then the elasticity of substitution must be less

---

[19] A few studies find capital shares in developing countries as high as two-thirds (See for example, Rodríguez and Ortega, 2006). On the other hand, Gollin (2002) documents capital shares closer to a third.
[20] See Henry (2007), pp. 897-900.

than or equal to 0.35. There is little consensus on the size of the elasticity of substitution. Early work estimated small elasticities that were statistically indistinguishable from zero.[21] More recent studies cannot reject the hypothesis that the elasticity of substitution is 1 (Caballero, 1994). Most relevant to the countries in this paper, Coulibaly and Millar (2007) estimate an elasticity of substitution of about 0.8 for South Africa. With a standard error of 0.08, the Coulibaly and Millar estimate could imply an elasticity as small as 0.64. With a change in capital growth of 5.5 percentage points, a capital share of 1/2, and an elasticity of substitution of 0.64, Equation (9) predicts that liberalization would generate a 4.3 percentage-point increase in wage growth.

We do not mean to push any particular value for the capital share. And it is not clear that we have a consensus estimate of the size of the elasticity of substitution in developed countries, let alone emerging economies. What is clear, however, is that if you want to maintain the assumption that liberalization has no impact on total factor productivity, then the observed increases in wage growth are consistent with the model only if you are willing to concede that the elasticity of substitution is substantially less than 1 (i.e., the world is not Cobb-Douglas). But if the elasticity of substitution is significantly less than one, then it is hard to understand how capital's income share remains constant (or increases) following the liberalization-induced fall in the cost of capital.

On the other hand, if you maintain that the world is Cobb-Douglas, then our wage results imply that liberalization has an impact on total factor productivity (TFP). In a Cobb-Douglas world with a capital share of one half, Equation (9) implies an increase in real wage growth of 2.75 percentage points-leaving a gap of roughly one percentage point to be explained. A gap of one percentage point per year would require a four percent increase in the level of factor

---

[21] For a survey of this literature see Chirinko (1993).

productivity over four years. If opening up brings about changes that raise an economy's permanent level of efficiency by four percent, then this will show up as a temporary increase in TFP growth during the transition.[22] One can imagine a number of channels that lie outside the confines of the Solow model through which liberalization raises efficiency by this magnitude over the course of a four year window.

For instance, liberalization may enable firms to import more efficient machines (e.g., tractors instead of hoes) that effectively shift the country's production technology closer to the world frontier. DeLong (2004) argues that after liberalizing the capital account "…developing countries…would enjoy the benefits from technology advances and from learning-by-doing using modern machinery." In other words, to the extent that technological progress diffuses from developed to developing countries, the importation of new machinery provides an important conduit through which the diffusion may occur (Eaton and Kortum, 2001a). Almost all of the world's research and development (R&D) takes place in a small number of industrial countries (Eaton and Kortum, 1999), and the same group of countries accounts for over 70 percent of the world's machine exports in a given year (Eaton and Kortum, 2001b; Alfaro and Hammel, 2007).

Evidence from the literature supports the conjecture that developing countries can import technological progress by liberalizing the capital account. In the immediate aftermath of liberalizations, firms in the manufacturing sector of developing countries accumulate capital at a faster rate than they did before the liberalization (Chari and Henry, 2008). Furthermore, these countries raise their rate of capital accumulation by importing more capital goods. As a result of

---

[22] While endogenous growth models such as Romer (1986) certainly allow for the possibility of permanent growth effects due to innovation, this view of the world strikes us as most relevant for countries that actually do the innovating. Emerging economies are more likely to be adopters of technology, engaged in a periodic process of capital upgrading and technological catch up that bears closer resemblance to periodic jumps in the level of TFP.

liberalization, the share of capital goods imports to total imports rises by 9 percent, and the share of total machine imports as a fraction of GDP rises by 13 percent (Alfaro and Hammel, 2007).

The observation that both imports of capital goods and total factor productivity rise in concert with liberalization lends credence to the notion that new capital goods embody technological progress and that developing countries can raise their growth rates of total factor productivity by liberalizing the capital account.[23] The observation is also consistent with work showing that cross-country variation in the composition of capital investment explains much of the cross-country variation in total factor productivity (Caselli and Wilson, 2003).

On the other hand, some argue that the simplest explanation of capital-account-liberalization-induced TFP growth lies with the economic reforms that accompany liberalization. Economic reforms improve resource allocation, essentially producing a one-time shift in the production function that temporarily raises the growth rate of TFP, without inducing technological process per se (Henry, 2003). Others posit that liberalization facilitates increased risk sharing, which might encourage investment in riskier, higher growth technologies (Levine, 1997; Levine and Zervos, 1998a). Yet another explanation is that capital account liberalization generates unspecified "collateral benefits" that increase productivity (Kose, Prasad, Rogoff, and Wei, 2006).

Sorting through competing explanations for the increase in total factor productivity following liberalizations is an important research challenge that lies beyond the scope of this paper. The bottom line of the discussion here is that the size of the increases in wage growth and productivity we report are consistent with the model that drives our estimation. Whether the primary source of those increases lies with capital deepening or increased total factor

---

[23]Also, in the spirit of Rajan and Zingales (1998), liberalization may improve domestic firms' access to external finance, which might in turn increase the rate at which firms import capital goods.

productivity depends on reasonable differences in views about the elasticity of substitution that have yet to be resolved in the literature.

6. Conclusion

In the process of debating the impact of trade on wages, international economists pay relatively little attention to the impact of trade in capital. Debating the costs and benefits of capital market liberalization on economic growth, macro and financial economists largely ignore the implications of increased capital market integration for wages. Yet labor income typically accounts for about two-thirds of GDP. Almost two decades after the advent of capital account liberalization in the developing world, our paper provides the first systematic analysis of the impact of liberalization on the level of real wages.

Increased capital market integration in the 1980s and 1990s sharply reduced the cost of capital for manufacturing firms in emerging economies. In response to the fall in their cost of capital, these firms installed new machinery, much of which was imported from abroad, and may have embodied substantial technological progress. The combination of capital deepening and embodied technological progress drove up the productivity of workers in the manufacturing sector. Accordingly, the demand for those workers increased, along with their real wage.[24]

While the focus of this paper is on the level of real wages, our findings also provide important clues about the rise in wage inequality in developing countries documented by Goldberg and Pavcnik (2007). If the liberalization-induced increase in wages was evenly distributed across skilled and unskilled workers in the manufacturing sector, then no increase in the skill premium would have occurred. However, two observations suggest that the increase in

---

[24] Cragg and Epelbaum (1996) and Behrman, Birdsall, and Szekely (2000) make a similar argument for Latin America.

manufacturing sector wages was probably concentrated among highly skilled workers. First, countries' imports of machinery and equipment rise substantially in the aftermath of capital account liberalizations and firms that import machinery and equipment generally employ a larger share of high-skilled workers than firms that do not import such capital (Harrison and Hanson, 1999). Second, work that is characterized as unskilled from a developed country's perspective may be skilled-labor intensive in comparison to typical domestic production activities in a developing country (Feenstra and Hanson, 1997, 2003).

While it seems plausible to consider that capital market liberalization contributed to increased wage inequality in developing countries during the 1980s and 1990s, it is no more than a conjecture because the economic model we employ makes no distinction between skilled and unskilled workers. Moving from conjecture to testable prediction would require a model with skilled labor, unskilled labor, and capital as three distinct factors of production. In a three-factor model, capital deepening could exacerbate wage inequality through a form of skill-biased technological change if capital is more substitutable for unskilled workers and more complementary to skilled workers. However, since we do not use such a model, and our data do not provide information about the skill composition of the labor force, we cannot test this prediction.

Be that as it may, the bottom line of this paper is that increased capital market integration raised the average standard of living for a significant fraction of the workforce in developing countries. If labor is mobile across sectors, then over time we would expect the productivity-driven wage gains in manufacturing to translate into higher incomes for workers elsewhere in the economy. The extent to which the labor market in these countries functions well enough to allow workers to respond to wage differentials across sectors is an important issue that lies

beyond the scope of this paper.[25] As the quality and breadth of data on labor markets in

developing countries continues to improve, future work may produce more definitive

conclusions.

---

[25] See Wacziarg and Seddon Wallack (2004) for an analysis of intersectoral mobility of labor in response to trade reforms.

Notes: The capital account liberalization dates identified in this table are the dates on which the eighteen countries in Column 1 eased restrictions prohibiting foreign ownership of domestic stocks. The liberalization dates in Column 2 are an amalgamation of those in Henry (2000), Levine and Zervos (1998b) and Bekaert and Harvey (2000). Columns 2 through 6 list the dates of major economic reforms that occurred around the same time as the capital account liberalizations. The stabilization program dates in Column 3 come from Henry (2002) and various issues of the IMF Annual Reports. Column 4 lists trade liberalization dates from Sachs and Warner (1995). The privatization dates in Column 5 come from the Privatization Data Base maintained by the World Bank. Finally, Column 6 lists the month and year that each country received debt relief under the Brady Plan. The debt relief dates come from Cline (1995), Lexis Nexis, and various issues of the *Economist Intelligence Unit*. **Venezuela reversed its trade liberalization reforms in 1993.

Table 2. **Real Wage Growth During Capital Account Liberalization Episodes.**
Panel A: Summary Statistics.

	(1)	(2)	(3)	(4)

Notes: Panel A provides summary statistics on real wage growth for each country in the sample. Column 1 shows the log real wage change from event year [0] to [3] for each country's liberalization episode. Column 2 presents the liberalization real wage change expressed relative to the country's mean log real wage change from [-3] to [0]. Column 3 is the liberalization log real wage change expressed relative to the contemporaneous mean log real wage change for the control group countries between years [0] and [3]. Column 4 presents the difference-in-difference log real wage change that subtracts the difference in the pre-liberalization wage change between the treatment and control groups from the quantity in column 3.

Table 2. **Real Wage Growth During Capital Account Liberalization Episodes.**
Panel B: Statistical Significance of Means in Panel A.

R-squared	0.132	0.149	0.152	0.136	0.132	0.139

Notes: Panel B presents the coefficient estimates on the liberalization dummy by individual year ranging from the liberalization year [0] up to five years following the liberalization [5]. The right hand side variable is log of the real wage change. Robust standard errors in parentheses. ***, **, * represent 1%, 5% and 10% levels of significance, respectively.

Table 4. Difference-in-Difference Estimation of the Impact of Liberalization on Real Wage Growth, Country Fixed Effects, Standard Errors Clustered by Year.

Panel A: Estimation window (3 years prior to 3 years following liberalization).

	(1)	(2)	(3)	(4)	(5)	(6)
Liberalization	0.043***	0.043***	0.042***	0.031**	0.041***	0.031***
	(0.011)	(0.011)	(0.01)	(0.011)	(0.009)	(0.011)
Trade		0.022				0.005
		(0.019)				(0.021)
Stabilization			0.046*			0.023
			(0.024)			(0.023)
Privatization				0.034*		0.029
				(0.019)		(0.023)
Brady Plan					0.055	0.041
					(0.035)	(0.031)
Constant	0.025	0.021	0.019	0.018	0.018	0.010
	(0.016)	(0.013)	(0.014)	(0.017)	(0.015)	(0.014)
Observations	152	152	152	152	152	152
R-squared	0.34	0.35	0.36	0.36	0.36	0.38

Notes: The estimation procedure is ordinary least squares. The estimation window utilizes data from three years before and after liberalization. All specifications cluster the standard errors by year to account for the possibility that shocks to wage growth are correlated across countries within a given year. Standard errors appear in parentheses and are clustered by year. The symbols (***), (**), and (*) represent significance levels of 1%, 5%, and 10%, respectively. For the regressions reported in Panel A, the left-hand-side variable is the change in the natural log of the real wage relative to the control group over the window three years prior to three years following the liberalization date. *LIBERALIZE* is a dummy variable that takes on the value of one in the year that country *i* liberalizes (year [0]) and each of the subsequent three years ([1] [2] and [3]). *TRADE, STABILIZE, PRIVATIZE,* and *BRADY* are dummy variables that take on the value one whenever a trade liberalization, inflation stabilization, privatization or Brady plan program takes place during country *i*'s capital account liberalization episode. All specifications contain twenty five country-specific dummy variables.

Table 4. Difference-in-Difference Estimation of the Impact of Liberalization on Real Wage Growth, Country Fixed Effects, Standard Errors Clustered by Year.
Panel B: Estimation Window (Full Sample)

	(1)	(2)	(3)	(4)	(5)	(6)

	(0.012)	(0.011)	(0.012)	(0.014)	(0.012)	(0.014)
Trade		0.017				0.017
		(0.014)				(0.014)
Stabilization			-0.020			-0.030
			(0.018)			(0.02)
Privatization				0.015		0.017
				(0.015)		(0.016)
Brady Plan					0.008	0.017
					(0.024)	(0.025)
Constant	0.021***	0.020***	0.022***	0.020***	0.021***	0.021***
	(0.006)	(0.006)	(0.006)	(0.006)	(0.006)	(0.006)
Observations	722	722	722	722	722	722
R-squared	0.11	0.11	0.11	0.11	0.11	0.12

Notes: The estimation procedure is ordinary least squares. All specifications cluster the standard errors by year to account for the possibility that shocks to wage growth are correlated across countries within a given year. Standard errors appear in parentheses and are clustered by year. The symbols (***), (**), and (*) represent significance levels of 1%, 5%, and 10%, respectively. For the regressions reported in Panel B, the left-hand-side variable is the change in the natural log of the real wage relative to the control group for the full sample of data around the liberalization date. LIBERALIZE is a dummy variable that takes on the value of one in the year that country i liberalizes (year [0]) and each of the subsequent three years ([1] [2] and [3]). TRADE, STABILIZE, PRIVATIZE, and BRADY are dummy variables that take on the value one whenever a trade liberalization, inflation stabilization, privatization or Brady plan program takes place during country i's capital account liberalization episode. All specifications contain twenty five country-specific dummy variables.

Table 5. Difference-in-Difference Estimation of the Impact of Liberalization on Real Wage Growth, Standard Errors Clustered by Year and Country.
Panel A: Estimation window (3 years prior to 3 years following liberalization).

	(1)	(2)	(3)	(4)	(5)	(6)
Liberalization	0.047***	0.048***	0.048***	0.038***	0.048***	0.039**
	(0.012)	(0.012)	(0.013)	(0.014)	(0.014)	(0.015)
Trade		0.019				0.021
		(0.021)				(0.021)
Stabilization			-0.033			-0.029

Privatization				0.029		0.030
				(0.025)		(0.027)
Brady Plan					-0.033	-0.027**
					(0.023)	(0.012)
Constant	0.023	0.019	0.027*	0.017	0.027*	0.020
	(0.017)	(0.016)	(0.014)	(0.019)	(0.015)	(0.016)
Observations	152	152	152	152	152	152
R-squared	0.05	0.055	0.062	0.066	0.062	0.092

Notes: The estimation procedure is ordinary least squares. The estimation window utilizes data from three years before and after liberalization. All specifications simultaneously cluster the standard errors in two dimensions: (1) by year to account for the possibility that shocks to wage and productivity growth are correlated across countries within a given year, and (2) by country to account for the possibility that shocks to wage and productivity growth are correlated over time within a given country. Standard errors appear in parentheses. The symbols (***), (**), and (*) represent significance levels of 1%, 5%, and 10%, respectively. For the regressions reported in Panel A, the left-hand-side variable is the change in the natural log of the real wage relative to the control group over the window three years prior and three years following the liberalization date. LIBERALIZE is a dummy variable that takes on the value of one in the year that country i liberalizes (year [0]) and each of the subsequent three years ([1] [2] and [3]). TRADE, STABILIZE, PRIVATIZE, and BRADY are dummy variables that take on the value one whenever a trade liberalization, inflation stabilization, privatization or Brady plan program takes place during country i's capital account liberalization episode.

Notes: The estimation procedure is ordinary least squares. All specifications contain year-specific and country-specific dummy variables. Standard errors appear in parentheses. The symbols (***), (**), and (*) represent significance levels of 1%, 5%, and 10%, respectively. For the regressions reported, the left-hand-side variable is the change in the natural log of employment over the full sample. LIBERALIZE is a dummy variable that takes on the value of one in the year that country i liberalizes (year [0]) and each of the subsequent three years ([1] [2] and [3]). TRADE, STABILIZE, PRIVATIZE, and BRADY are dummy variables that take on the value one whenever a trade liberalization, inflation stabilization, privatization or Brady plan program takes place during country i's capital account liberalization episode.

Appendix A

Countries that had not liberalized as of 1997: Algeria, Bangladesh, Barbados, Benin, Burkina Faso, Cameroon, Central African Republic, Chad, Congo, Costa Rica, Cote D'Ivoire, Dominican Republic, Ecuador, El Salvador, Fiji, Gabon, Gambia, Ghana, Guatemala, Guyana, Haiti, Honduras, Iceland, Iran, Jamaica, Kenya, Kuwait, Madagascar, Malawi, Mali, Malta, Mauritius, Nepal, Nicaragua, Niger, Oman, Paraguay, Peru, Rwanda, Saudi Arabia, Senegal, Sierra Leone, Syrian Arab Republic, Togo, Trinidad and Tobago, Tunisia, Uruguay, Zambia.

Countries that liberalized before 1980: Australia, Austria, Denmark, Finland, Ireland, Norway.

Countries that liberalized between 1980 and 1997: Argentina, Brazil, Chile, Colombia, Egypt, Greece, India, Indonesia, Israel, Jordan, Malaysia, Mexico, Morocco, New Zealand, Nigeria, Pakistan, Philippines, Portugal, South Africa, Spain, Sri Lanka, Thailand, Turkey, Venezuela, Zimbabwe.
