ABSTRACT

Specialization alters the incidence of manufacturing trade costs to buyers and sellers, with pro-and anti-globalizing effects on 76 countries from 1990-2002. The structural gravity model yields measures of Constructed Home Bias (the ratio of predicted local trade to predicted frictionless local trade) and the Total Factor Productivity effect of changing incidence. A bit more than half the world's countries experience declining CHB and rising TFP. The correlation between the two is negative but well below perfect. The effects are big for the outliers. A novel test of the structural gravity model shows it comes very close in an economic sense.

Specialization is revealed in this paper as a powerful force churning the world’s economies from 1990 to 2002. Trade costs inferred from gravity are large and vary with distance, so the shifts in the location of production and consumption due to specialization and asymmetric aggregate growth must be changing ‘average’ trade costs. But what is ‘average’, and isn’t incidence what matters? This paper provides answers. They reveal both pro- and anti-globalizing effects of specialization — some countries become more open to trade while others become less open, all despite unchanging bilateral trade costs. The changing incidence has significant real output effects in manufacturing — some countries gain while others lose. The effects are big for the extremes.

The rise of manufacturing in developing countries and its decline in developed ones are revealed by big shifts in key countries’ production shares. For example, between 1990 and 2002, China’s share of world manufactures rises from 3.1% to 7.6% while Japan’s falls from 19.7% to 13.7%. China’s high aggregate growth compared to Japan’s very low growth is not the only force at work, as reallocation within manufacturing shows up in a comparison of sectoral shares. Japan’s world share of Beverages and Tobacco actually rises while its share of Paper Products falls only marginally. China’s share of every sector rises but some less than double (e.g. Printing) while others (e.g., Apparel, Transport) quadruple. Increasing specialization due to comparative advantage is indicated by a fall in the correlation between national shares of world manufacturing output and expenditure across 18 3 digit manufacturing sectors and 76 countries from 1990 to 2002. Table 1 highlights the change in correlation in a few key sectors. For all goods and countries the fall is from 0.97 to 0.94 (see column 1).

Table 1: Correlations: Output and Expenditure Shares

	(1)	(2)	(3)	(4)
Year	All Manufacturing	Apparel (322)	Leather (323)	Food (311)
1990	0.97	0.94	0.82	1.00
2002	0.94	0.74	0.70	1.00

This table reports correlations between world output and expenditure shares for three 3-digit ISIC categories and total manufacturing in 1990 and 2002.

The decrease in total manufacturing is driven by sectors such as Apparel and Leather (see

columns 2 and 3). In contrast, change in the impact of comparative advantage has played no role for categories such as Food (see column 4).

The main focus of the paper is measures of the buyers' and sellers' incidence of trade costs and of Constructed Home Bias (CHB), the ratio of predicted local trade to predicted frictionless local trade. Our measures of theoretically consistent average incidence are implicit functions of world output and expenditure shares derived from the structural gravity model. Changes in the incidence of trade costs are equivalent to (the negative of) changes in the incidence of Total Factor Productivity (TFP) in distribution,¹ changing real output. A bit more than half the world's countries experience declining CHB and rising real output while the remainder of countries experience rising CHB and falling real output. Fast growers with rising shares of world shipments tend to experience the biggest declines in home bias (e.g., China's home bias falls 51% and Ireland's 53% over the 12 years) and rises in the incidence of TFP (China's TFP incidence rises 16% and Ireland's 5%) while unfortunate parts of the former Soviet Union experience large increases in home bias (203% in Ukraine and 154% in Azerbaijan) and falls in TFP incidence (5% and 26% respectively).²

Trade costs are treated as constant in the main account of the paper because the gravity model coefficients are close to constant in all the variants of the model estimated and discussed below, and including their inter-temporal variation makes essentially no difference to the main results. Constant gravity coefficients need not be inconsistent with falling trade cost *levels* because the structural gravity model implies that only *relative* trade costs can be identified: the bilateral pattern of trade is invariant to uniform proportional changes in bilateral trade costs (including costs of local shipment).

We estimate with disaggregated data, a highly consequential departure from the usual

¹The model permits the effect of changing composition of trade to be converted into an equivalent technology change, as we show below. In what has become a common abuse of terminology, TFP refers here to the Solow residual, not a pure technological change.

²The churning among the world's economies revealed here is in sharp contrast to Anderson and Yotov (2009, forthcoming). Their portrayal of Canada's provinces over the same period uses the same methods we apply here. All Canadian provinces experienced decreased home bias and increased real output as Canada integrated with the USA and Mexico. The difference is that the present study covers (most) countries in a world economy with both fast (China, India) and slow (Japan) growing and specializing economies.

practice. We find that aggregation substantially understates trade costs and CHB, and reduces the dispersion of CHB and of real output changes.

The paper also provides a novel test of the structural gravity model.³ The structural gravity model comes remarkably close in an economic sense to accurately representing the data generating process across commodities, countries and time.

Section 1 reviews the structural gravity model and its implications to derive measures of buyers' and sellers' incidence of trade costs, CHB and the real output effect changing incidence of TFP in distribution. Section 2 describes the econometric specification. Section 3 describes the data. Section 4 presents the empirical results. Section 5 concludes.

1 The Structural Gravity Model

Our development follows Anderson (1979) in using the Armington assumption and CES preferences to derive gravity. It treats the total supply to all destinations and total expenditure on goods from all origins as exogenous.⁴

Let X_{ij}^k denote the value of shipments at destination prices from origin i to destination j in goods class k . Let $t_{ij}^k \geq 1$ denote the variable trade cost factor on shipment of goods from i to j in class k , p_i^{*k} denote the factory gate price, hence destination prices are $p_i^{*k} t_{ij}^k$. Let E_j^k denote the expenditure at destination j on goods class k from all origins, while Y_i^k denotes the sales of goods at destination prices from i in goods class k to all destinations.

³Earlier gravity model estimation using aggregate trade flows often found GDP coefficient point estimates differing significantly from the theoretically indicated value of 1. But these findings are not legitimate tests of the structural gravity model because aggregate gravity estimation suffers from aggregation bias and GDP is not the appropriate activity variable.

⁴The CES-Armington model nests inside many full general equilibrium models characterized by trade separability: two stage budgeting and iceberg trade costs \Rightarrow distribution uses resources in the same proportions as production. The weights in the CES preferences can be endogenized with monopolistic competition structure (Bergstrand, 1989) while sector supply is determined by Heckscher-Ohlin production structure. Eaton and Kortum (2002) derive an observationally equivalent structural gravity setup from homogeneous goods combined with Ricardian technology and random productivity draws, a setup extended to multiple goods classes by Costinot and Komunjer (2007).

The CES demand function (for either final or intermediate goods) gives:

$$X_{ij}^k = (\beta_i^k p_i^{*k} t_{ij}^k / P_j^k)^{1-\sigma_k} E_j^k. \quad (1)$$

σ_k is the elasticity of substitution parameter for k and β_i^k is a share parameter. The CES price index is $P_j^k = [\sum_i (\beta_i^k p_i^{*k} t_{ij}^k)^{1-\sigma_k}]^{1/(1-\sigma_k)}$.

Market clearance implies: $Y_i^k = \sum_j (\beta_i^k p_i^{*k})^{1-\sigma_k} (t_{ij}^k / P_j^k)^{1-\sigma_k} E_j^k$. Define $Y^k \equiv \sum_i Y_i^k$ and divide the market clearance equation by Y^k . The result requires that world supply shares be equal to world expenditure shares. So far as seller i is concerned, with globally common CES preferences, the ‘world expenditure shares’ are equivalently generated by

$$(\beta_i^k p_i^{*k} \Pi_i^k)^{1-\sigma_k} = Y_i^k / Y^k, \quad (2)$$

where $\beta_i^k p_i^{*k} \Pi_i^k$ is the world market quality adjusted price of variety i of good k and $\Pi_i^k \equiv \sum_j (t_{ij}^k / P_j^k)^{1-\sigma_k} E_j^k / Y^k$ is the ‘world’ market average sellers’ incidence. In (2) the CES ‘world’ price index of k is understood to be equal to 1 because summing (2) yields:

$$\sum_i (\beta_i^k p_i^{*k} \Pi_i^k)^{1-\sigma_k} = 1. \quad (3)$$

Next, use (2) to substitute for $\beta_i^k p_i^{*k}$ in (1), the market clearance equation and the CES price index. This yields the structural gravity model:

$$X_{ij}^k = \frac{E_j^k Y_i^k}{Y^k} \left(\frac{t_{ij}^k}{P_j^k \Pi_i^k} \right)^{1-\sigma_k} \quad (4)$$

$$(\Pi_i^k)^{1-\sigma_k} = \sum_j \left(\frac{t_{ij}^k}{P_j^k} \right)^{1-\sigma_k} \frac{E_j^k}{Y^k} \quad (5)$$

$$(P_j^k)^{1-\sigma_k} = \sum_i \left(\frac{t_{ij}^k}{\Pi_i^k} \right)^{1-\sigma_k} \frac{Y_i^k}{Y^k}. \quad (6)$$

Π_i^k is called outward multilateral resistance by Anderson and van Wincoop (2003), here

interpreted as sellers' incidence. Then t_{ij}/Π_i^k is the bilateral buyers' incidence. P_j^k generated by (5)-(6) is called inward multilateral resistance and is also the CES price index of the demand system. P_j^k is interpreted here as buyers' incidence because it is a CES index of the bilateral buyers' resistances on flows from i to j in class k , the weights being the frictionless trade equilibrium shares $\{Y_i^k/Y^k\}$. It is as if buyers at j pay a uniform markup P_j^k for the bundle of goods purchased on the world market.⁵

Fixed costs help to explain the many zeroes found in bilateral trade flows, a feature even more prominent in disaggregated data.⁶ Without an appropriate treatment for fixed costs, the response of trade volume on the extensive margin is included in the variable cost measuring response on the intensive margin. Helpman, Melitz and Rubinstein (2008) develop a treatment of fixed costs and apply it to aggregate trade flow data. The assumptions of the model, especially the exclusion restriction that permits identification, are controversial, but we apply their method to our disaggregated data as part of robustness analysis. Our main results are all invariant to the method of estimation because it turns out that switching methods shifts the gravity coefficients equiproportionately, so that the implied t 's are shifted equiproportionately. Since gravity can only identify relative trade costs anyway, differences in estimation methods wash out with the normalizations.

1.1 Calculating Incidence and Constructed Home Bias

Since system (5)-(6) solves for $\{\Pi_i^k, P_j^k\}$ only up to a scalar for each class k , an additional restriction from a normalization is needed.⁷ Within sectors, relative multilateral resistances

⁵ $\{P_j^k \Pi_i^k\}$ is the general-equilibrium-consistent aggregate analog to the one-good partial equilibrium incidence decomposition. If the actual set of bilateral trade costs is replaced by $\tilde{t}_{ij}^k = P_j^k \Pi_i^k$, all budget constraints and market clearance conditions continue to hold, and factory gate prices and aggregate supply and expenditure shares remain constant (Anderson and van Wincoop, 2004). The bilateral shipment pattern shifts to that of the frictionless equilibrium. This hypothetical general equilibrium plays a role analogous to the hypothetical frictionless equilibrium in the one good partial equilibrium incidence analysis.

⁶Trade cost still has the iceberg form because both fixed and variable costs absorb a portion of the good.

⁷If $\{\Pi_i^0, P_j^0\}$ is a solution then so is $\{\lambda \Pi_i^0, P_j^0/\lambda\}$.

are what matter,⁸ so alternative normalizations are admissible for convenience in the absence of information on $\beta_i^k p_i^{*k}$'s. Our empirical procedure is $P_i^k = 1, \forall k$ where i is the US. None of our main results depend on the normalization, as we will explain further as needed.⁹

(4) leads to a useful quantification of home bias that summarizes the effect of all trade costs acting to increase each country's trade with itself above the frictionless benchmark, $E_i^k Y_i^k / Y^k$.¹⁰ Constructed Home Bias is defined by

$$CHB_i^k \equiv (t_{ii} / \Pi_i^k P_i^k)^{1-\sigma_k}. \quad (7)$$

CHB is the ratio of predicted to frictionless internal trade. Two regions i and j with the same internal trade cost $t_{ii} = t_{jj}$ may have quite different CHB's because $\Pi_i^k P_i^k \neq \Pi_j^k P_j^k$.

1.2 TFP, Incidence and Real Output

The changing composition of production and expenditure obviously drives changes in 'average' measures of trade costs, raising the classic index number question of what average to use. We focus on national changes in the incidence of trade costs because in a global economy these induce real national output changes. These in turn would be picked up in national measures of the Solow residual and interpreted as changes in productivity. In principle our methods take a step toward being able to extract the changing incidence of TFP in distribution from the standard calculations of Solow residuals.

To clarify the difference of our incidence measures from standard TFP-type measures of productivity in distribution, we first develop TFP measures of the productivity of distribution and compare them to incidence measures. Then we analyze the real output effects of changes in the incidence of TFP in distribution.

⁸Specifically, the trade flow in equation (4) is not affected by changes in the scalar λ of the preceding footnote.

⁹There is no conflict with the theoretically required normalization (3). Normalization of a single P together with the rest of the CES demand system structure implies a set of prices $(\beta_i \tilde{p}_i)^{1-\sigma}$'s that must be consistent with the theoretical normalization of the Π 's. See the Appendix for more discussion.

¹⁰ $t_{ij}^k = 1, \forall i, j$ implies $P_j^k = \Pi_i^k = 1, \forall i, j$, using (5)-(6).

Sectoral TFP friction in distribution is defined by the uniform friction that preserves the value of sectoral shipments at destination prices: $\bar{t}_j^k = \sum_h t_{jh}^k y_{jh}^k / \sum_h y_{jh}^k$ where y_{jh}^k denotes the number of units of product class k received from j at destination h . The iceberg metaphor captures the technological requirement that distribution requires resources in the same proportion as does production, so in product class k it takes $t_{jh}^k y_{jh}^k$ of origin j resources to deliver y_{jh}^k to destination h . \bar{t}_j^k is a Laspeyres index of outward trade frictions facing seller j in good k . Aggregate TFP friction for country j is similarly given by $\sum_{k,h} \bar{t}_j^k p_j^{*k} y_{jh}^k / \sum_{k,h} \tilde{p}_j^k y_{jh}^k$,¹¹ a Laspeyres index of outward trade costs between sellers in j and their buyers in all markets. When all goods are final goods this expression is equal to the ratio of output at delivered prices to the value of output at factory gate efficiency unit prices.

While conceptually clean and useful for analyzing productivity of the world economy as a whole, TFP is misleading for purposes of understanding comparative economic performance and the national patterns of production and trade in a globally interdependent world. Like sectoral TFP friction \bar{t}_k^j , multilateral resistance aggregates bilateral frictions, but the multilateral resistances solved from (5)-(6) are general equilibrium *incidence* measures. In contrast, \bar{t}_j^k can be interpreted as sellers' incidence only under the partial equilibrium and inconsistent assumption that all incidence falls on the seller j . Our results show that in practice these differences are significant: Laspeyres TFP measures and the incidence of TFP differ in magnitude and in the case of inward measures the correlation between them is low.¹²

We calculate measures of change in real output using the changes in levels of multilateral resistances (one for each commodity class, country and year) and the shares of shipments and expenditures (one for each commodity class, country and year). The basic idea is seen

¹¹The procedures straightforwardly extend to include pure productivity frictions in which case the factory gate price is deflated by the pure technology friction.

¹²An alternative measure proposed by Redding and Venables (2004) resembles multilateral resistance but does not measure incidence. Their measure of 'market access' uses essentially the same formula as (5) while their measure of 'supplier access' uses the CES price index formula $P_j^k = [\sum_i (\beta_i^k p_i^{*k} t_{ij}^k)^{1-\sigma_k}]^{1/(1-\sigma_k)}$. These variables are constructed without taking account of the simultaneous determination of the two variables, so they do not measure incidence.

with a local approximation formula:

$$\widehat{G}_j = - \sum_k w_j^k \widehat{\Pi}_j^k - \sum_k \omega_j^k \widehat{P}_j^k, \quad (8)$$

where w_j^k denotes the share of total shipments from origin j due to good k and ω_j^k denotes the share of total expenditure in destination j (on intermediate as well as final goods) due to good k , and the circumflex (hat) denotes the percentage change in the deflated multilateral resistance. The technical appendix explains the conceptual foundation of this procedure.

With a 12 year time span, there are several plausible choices for applying the basic idea of the formula. A fixed weight approach applies some sensible shipment and expenditure weights, in our case the shipment and expenditure weights for 1996, the middle year of the panel, and uses the 12 year percentage change in multilateral resistances for the “price” variables in (8).

A more elaborate chain weights approach uses arithmetic averages of yearly adjacent shares for weights and calculates the yearly percentage change in G_j , adding the changes up to obtain the 12 year cumulative change. In practice, recognizing discrete changes, we integrate (8) over the annual intervals, hence use differentials of logs on both sides for the “price” variables. The cumulative effect is thus obtained by exponentiating

$$\ln[G_j(2002)/G_j(1990)] = - \sum_k \sum_{\tau=1}^{12} \widetilde{w}_j^k(\tau) \widehat{\Pi}_j^k(\tau) - \sum_k \sum_{\tau=1}^{12} \widetilde{\omega}_j^k(\tau) \widehat{P}_j^k(\tau) \quad (9)$$

Here,

$$\widetilde{w}_j^k(\tau) \equiv \frac{w_j^k(2002 - \tau + 1) + w_j^k(2002 - \tau)}{2}$$

and analogously for the ω ’s. (9), after exponentiation, is a Tornqvist approximation to a Divisia index of G . The chain weights approach has significant advantages when countries experience large shifts in their cross-commodity composition of production and expenditure, as many do from 1990 to 2002. Like CHB, G is invariant to the normalization used to calcu-

late the P 's and Π 's in (8) or (9). This is because any rescaling raises all P 's proportionally while lowering all Π 's in the same proportion.

2 Econometric Specification

Two steps complete the econometric model. First, we approximate the unobservable bilateral trade costs t_{ij}^k with a set of observable variables that are now standard in the gravity literature:¹³

$$t_{ij}^k^{1-\sigma} = e^{\beta_1^k \ln DIST_{ij} + \beta_2^k BRDR_{ij} + \beta_3^k LANG_{ij} + \beta_4^k CLNY_{ij} + \beta_5^k SMCTRY_{ij}}. \quad (10)$$

Here, $\ln DIST_{ij}$ is the logarithm of bilateral distance between trading partners i and j . $BRDR_{ij}$ captures the presence of contiguous borders. $LANG_{ij}$ and $CLNY_{ij}$ account for common language and colonial ties, respectively. Finally, $SMCTRY_{ij}$ is a dummy variable equal to 1 when $i = j$ and zero elsewhere. This variable captures the effect of crossing the international border by shifting up internal trade, all else equal. Using the internal trade dummy has the advantage of being an exogenous variable that picks up all the relevant forces that discriminate between internal and international trade. It also preserves comparability with the specification used by Anderson and Yotov for Canadian provincial trade. Ideally, we should estimate $SMCTRY$ as a country-specific, time-varying, directional dummy variable.¹⁴ Lacking observations for enough degrees of freedom, we impose a common coefficient β_5^k for each commodity and time period. Furthermore, in the panel gravity estimations, we impose the restriction of time-invariant effects.¹⁵

¹³See Anderson and van Wincoop (2004) for a discussion of trade costs.

¹⁴Using regional trade data for Canada's provinces, Anderson and Yotov (2009) estimate a specification with directional border effects to find that they are not identified. In the present context with only national data, the directional specification is not feasible due to lack of degrees of freedom.

¹⁵Time-invariance is less at odds with reality than at first appears. While 1990-2002 includes major policy changes because of the Uruguay Round and the formation of the WTO, the previous gravity literature shows that policy is a small part of the border barrier. See for example Anderson and van Wincoop (2003) and Anderson and Yotov (2009).

Next, we substitute (10) for t_{ij} into (4) and then we expand the gravity equation with a multiplicative error term, ϵ_{ij}^k , to get:

$$X_{ij}^k = \frac{Y_i^k E_j^k}{Y^k} \left(\frac{t_{ij}^k}{\Pi_i^k P_j^k} \right)^{1-\sigma_k} \epsilon_{ij}^k. \quad (11)$$

Estimating (11) requires accounting for the unobservable multilateral resistance terms. Anderson and van Wincoop (2003) use a full information method incorporating (5)-(6). We follow Feenstra (2004), who advocates the directional (source and destination), country-specific fixed effects approach, which is easier to implement and also produces consistent estimates. Moreover, fixed effects do not impose unitary elasticities on $P^{\sigma-1}$, $\Pi^{\sigma-1}$ and allow for other unobservable country/product effects not contained in the theoretical gravity model, a less restrictive approach that nests the structural gravity model. In order to control for the unobservable MRs, the observable Y 's and E 's and other unobservables, we employ directional, country-specific fixed effects in our yearly estimations, and we use time-varying, directional, country-specific dummies to control for the MRs in the panel estimations.¹⁶

Another econometric challenge in gravity-type estimations is the presence of a large number of zero bilateral trade flows, which cannot be captured by a simple log-linear OLS regression. Santos-Silva and Tenreyro (2007) show that the truncation of trade flows at zero biases the standard OLS approach. In addition, they argue that not accounting for trade data heteroscedasticity in the log-linear OLS regressions produces inconsistent coefficient estimates. To account for heteroscedasticity and to utilize the information carried by the zero trade flows, Santos-Silva and Tenreyro suggest estimating the gravity equation in multiplicative form using the Poisson pseudo-maximum-likelihood (PPML) estimator.

The PPML estimator is used to obtain the main results in this study. However, in order to test the robustness of our findings, we also experiment with log-linear OLS regressions and the

¹⁶In Section 4.5 below we analyze the relationship of the estimated fixed effects to the calculated multilateral resistances and the output and expenditure shares. The results suggest that the structural gravity model comes very close in an economic sense to accounting for the data, but is not the whole story.

two-step selection procedure of Helpman, Melitz and Rubinstein (2008, henceforth HMR). HMR model selection where exporters must absorb some fixed costs to enter a market. Their model controls simultaneously for unobserved heterogeneity (the proportion of exporting firms) and for sample selection. In addition to checking the robustness of our results, we are curious to see how do the PPML and the HMR models compare to the standard OLS treatment of gravity when the estimations are performed with disaggregated data.

The PPML and OLS techniques estimate the following econometric specification for each class of commodities in our sample:

$$\begin{aligned} \ln X_{ij,t} = & \beta_0 + \beta_1^k \ln DIST_{ij,t} + \beta_2^k BRDR_{ij,t} + \beta_3^k LANG_{ij,t} + \beta_4^k CLNY_{ij,t} + \\ & + \beta_5^k SMCTRY_{ij,t} + \eta_{i,t}^k + \theta_{j,t}^k + \epsilon_{ij,t}^k. \end{aligned} \quad (12)$$

HMR differs by including a volume effect reflecting selection. In (12) $X_{ij,t}$ is bilateral trade (in levels) between partners i and j at time t .¹⁷ $\eta_{i,t}$ denotes the set of time-varying source-country fixed effects that control for the outward multilateral resistances along with total sales $Y_{i,t}^k$. $\theta_{j,t}^k$ denotes the fixed effects that control for the inward multilateral resistances along with total expenditures $E_{j,t}^k$.¹⁸ The country fixed effects also reflect the effect of border barriers varying by country, sector and time.

3 Data Description

The data covers 1990-2002 for 76 trading partners. The countries are listed in Data Appendix.¹⁹ Data availability allowed us to investigate 18 commodities aggregated on the

¹⁷Even though we experiment with yearly estimations, our main results are obtained from panel data. As noted in Cheng and Wall (2005), “Fixed-effects estimations are sometimes criticized when applied to data pooled over consecutive years on the grounds that dependent and independent variables cannot fully adjust in a single year’s time.” To avoid this critique, we use only the years 1990, 1994, 1998, and 2002. It turns out, however, that the gravity estimates are not very sensitive to the use of alternative lags.

¹⁸In a static setting, the structural gravity model implies that the income and the expenditure elasticities of bilateral trade flows are unity. Olivero and Yotov (2009) show that the income elasticities are not necessarily equal to one in a dynamic setting.

¹⁹Country coverage was predetermined mainly by the availability of sectoral level production data.

basis of the United Nations’ 3-digit International Standard Industrial Classification (ISIC) Revision 2.²⁰ To estimate gravity and to calculate the various trade cost indexes, we use industry-level data on bilateral trade flows and output, and we construct expenditures for each trading partner and each commodity class, all measured in thousands of current US dollars for the corresponding year. In addition, we use data on bilateral distances, contiguous borders, colonial ties, common language, and industry level data on elasticity of substitution. The Data Appendix provides a detailed description of the data sources and the procedures used to construct all variables employed in our estimations and analysis.²¹

4 Empirical Results

4.1 Gravity Estimation Results

Tables 2-4 report the PPML panel results obtained with robust standard errors clustered by trading pair.²² Overall, the disaggregated gravity model works well. The gravity estimates vary across commodities in a sensible way. Importantly, the coefficients are relatively stable over time for any given commodity category. To measure the movement of our gravity estimates over time, we construct the percentage changes in the yearly estimates for the period 1990-2002: $\% \Delta \hat{\Theta} = 100 \times \frac{\hat{\Theta}_{2002} - \hat{\Theta}_{1990}}{\hat{\Theta}_{1990}}$, where $\hat{\Theta}$ is the yearly PPML gravity coefficient estimate of any of the regressors in our estimations.²³ In what follows, we discuss the estimates and the evolution over time for each of the covariates in our regressions.

²⁰The complete United Nations’ 3-digit International Standard Industrial Classification consists of 28 sectors. We combine some commodity categories when it is obvious from the data that countries report sectoral output levels in either one disaggregated category or the other. Our commodity categories are: 1 Food; 2 Beverage and Tobacco; 3 Textiles; 4 Apparel; 5 Leather; 6 Wood; 7 Furniture; 8 Paper; 9 Printing; 10 Chemicals; 11 Petroleum and Coal; 12 Rubber and Plastic; 13 Minerals; 14 Metals; 15 Machinery; 16 Electric; 17 Transportation; and, 18. Other. A detailed conversion table between ours and the UN 3-digit ISIC classification is available upon request.

²¹Tables with summary statistics and the data set itself are available upon request from the authors.

²²Comparison between estimates obtained with and without clustering reveal that the clustered standard errors are a bit larger. This suggests positive intracluster correlations, as expected.

²³These indexes, the corresponding standard errors (computed with the Delta method), as well as the disaggregated gravity estimates for individual years, are available upon request.

Distance (DIST1-DIST4). The estimated distance elasticities are always negative and, in most cases, significant at any level.²⁴ The estimates are only partially in accordance with those Eaton and Kortum (2002) based on aggregate data. They report that the estimate of the distance coefficient for shorter distances is larger (in absolute value) than for longer distances. For most commodities, we find a non-monotonic (inverse u-shape) relationship between distance and trade flows.²⁵ Distance elasticities vary greatly by sector. Tables 2-4 show that, regardless of the interval, distance is a bigger obstacle to trade for some commodities, such as Wood, Minerals, Beverages and Tobacco, and Paper, while for other categories, such as Machinery and Textiles, distance is less of an impediment to trade.²⁶ Based on the percentage changes in the yearly distance estimates (available upon request) we conclude that the effects of distance on trade are flat over the period of investigation.²⁷ All findings regarding the evolution of the distance estimates over time are consistent across the four intervals.

Common Border (BRDR). All else equal, countries that share a common border trade more with each other. Estimated coefficients on the contiguity variable BRDR are always positive, large and significant. The category of Beverages and Tobacco products is the only exception, for which the coefficient estimate on BRDR is neither economically nor statistically significant. Contiguity effects vary significantly across commodities. For example, each of the positive contiguity effects for Wood, Furniture, and Printing products are more than twice those for Chemical products. Finally, contiguity effects are flat over the period

²⁴Textiles, Apparel, Leather and Electric products are the only exceptions, for which the estimates are not significant for one or more of the distance intervals, however, the overall effect of distance is negative and significant.

²⁵The negative effect of distance on bilateral trade is smallest (sometimes insignificant) for the countries that are less than 3000 kilometers away from each other. Depending on the commodity, the effects of distance are largest for country pairs in either the second interval, of [3000, 7000) kilometers, or in the third interval, of [7000, 10000) kilometers. For a few sectors, such as Textiles, Chemicals, Petroleum and Coal, and Metals, the estimate of the distance coefficient for longer distances is always larger (in absolute value) than for shorter distances.

²⁶The estimates of the distance elasticities for Leather and Electrical Products are not statistically significant.

²⁷Without any exception, for all of the commodities in our sample the changes in the effects of distance are mostly small in magnitude and never statistically significant.

1990-2002.²⁸

Common Language (LANG). Sharing a common official language facilitates bilateral trade. About two-thirds of the estimated language effects from tables 2-4 are positive and significant at any level. Insignificant LANG effects are found for Furniture, Rubber and Plastic, Electrical Products, Transportation and Other manufacturing products. The variation in the magnitude of the coefficients across commodities makes intuitive sense. Thus, for example, Printing and Publishing is the category with largest LANG estimate. The evolution of language effects over time is essentially flat.²⁹

Colonial Ties (CLNY). Tables 2-4 indicate that colonial ties increase bilateral, commodity-level trade flows only for a few product categories. As compared to the other gravity variables, ‘colonial ties’ is the regressor with least explanatory power. Only one-third of the CLNY coefficient estimates are positive and significant, and, in most cases, marginally so.³⁰ Furthermore, the significant estimates are small in magnitude. Colonial ties matter most for ‘Printing and Publishing’. The explanation is that very often countries involved in colonial relationships share the same language. Overall, our estimates suggest that the effects of colonial ties have slowly disappeared during the 90s.

Same Country (SMCTRY). International borders reduce trade, all else equal, as is well established in the gravity literature. Tables 2-4 confirm this finding at the commodity level. All estimates of the coefficients on SMCTRY (the dummy variable capturing internal trade) are positive, large, and significant at any level. Not surprisingly, Food, Beverages and Tobacco, and Printing and Publishing are among the categories with highest domestic bias in trade, while Machinery and Transportation, which are industries with clear patterns of international specialization, are among the categories with lowest SMCTRY estimates. Contrary to our prior expectations, we obtain a very large SMCTRY estimate for Petroleum

²⁸Almost all estimates of the percentage changes are small in magnitude and none of them are statistically significant.

²⁹We observe both increases and decreases in the estimates of LANG, but none are statistically significant.

³⁰Less than one third of the yearly estimates of the coefficients on CLNY are significant. For the few products for which the yearly estimates are significant, we find that the CLNY effects have decreased over time, but the decrease is not statistically significant.

and Coal. A possible explanation is that this category includes a large line of goods produced in domestic refineries and plants. Also, the large average effect may be driven by outliers with large home bias in petroleum consumption due to heavy subsidization.

Overall, the SMCTRY effects are persistent over time. The percentage changes of the yearly estimates are mostly small in magnitude and not statistically significant. There are a few categories for which we estimate a significant decrease in the domestic bias over the period 1990-2002. These commodities are Textiles, Apparel, Metals, and Electrical products. For Textiles and Apparel, the entry of China into the WTO is an obvious explanation despite the contrary effect of the MFA, none of which is modeled. Petroleum and Coal products is the only category for which we find an increase in domestic bias. Possible explanations for this finding include recent wars and political conflicts, and efforts to improve energy security.

In order to abstract from any effects due to changes in the yearly gravity estimates,³¹ we choose to employ the panel PPML estimates in the calculation of the trade costs indexes below. As more justification for this procedure we construct correlations (by product) between the panel PPML estimates and their yearly PPML counterparts. All correlation indexes are very large (above 0.9) and significant.³² This suggests that the two estimation sets (panel and yearly) can be used interchangeably in the calculation of the trade costs indexes.

As a robustness check, we compare the panel PPML estimates against two alternative econometric specifications, a log-linear OLS and a two-step HMR procedure. Santos-Silva and Tenreyro (2006) criticize the standard log-linear OLS approach to estimate gravity as inappropriate. They argue in favor of the PPML estimator and find significant biases in the OLS gravity estimates. In accordance with their findings, but using disaggregated data, we find an upward bias in the OLS estimates, especially in the coefficient estimates of distance and of colonial ties. These results are consistent in both the panel and the yearly estimations. More importantly however, we establish almost perfect correlation between the OLS (both

³¹In a few instances, we obtain wrong-sign estimates. For example, we estimate a positive and significant effect of distance on bilateral trade for Textiles in 1990.

³²These numbers, along with the yearly PPML estimates, are available upon request.

yearly and panel) estimates and the PPML gravity estimates.³³ Remembering that the gravity system identifies only relative trade costs, the very high correlation between the PPML and the OLS estimates suggests that the two sets are equally good proxies for the unobservable bilateral trade costs and can be used interchangeably for our purposes.

Finally, we compare the panel PPML estimates to estimates obtained with the two-step HMR method, where exporters must absorb some fixed costs to enter a market. The model controls simultaneously for sample selection bias and for unobserved heterogeneity bias. To keep the sample size as large as possible, we follow Helpman, Melitz and Rubinstein (2008) in using religion as the exclusionary variable that permits identification. We apply the HMR cubic polynomial specification to control for the biases caused by the unobserved firm heterogeneity along with the Heckman (1979) sample selection correction to obtain both panel as well as yearly estimates. The disaggregated HMR estimates support the aggregate findings. Both the selection and the unobserved heterogeneity biases are significant, which leads to exaggerated OLS estimates. Most important for our purposes is the almost perfect correlation between the panel PPML estimates and the HMR panel and yearly counterparts.³⁴ PPML and HMR estimates are thus essentially equivalent for the calculation of the trade cost indexes.

We view our disaggregated gravity results as fairly convincing. The standard gravity variables pick up a significant portion of the variability of bilateral trade flows at the commodity level. In addition, the disaggregated coefficient estimates are stable over time and their signs and magnitude make intuitive sense. Overall, our estimates are comparable to the those obtained with aggregate data, however we also reveal some important differences and additional insights.

³³Correlation coefficients and OLS estimation results (panel and yearly) are available upon request.

³⁴Correlation coefficients and HMR estimation results (panel and yearly) are available upon request.

4.2 Multilateral Resistance Indexes

Multilateral resistance measures the incidence of the global set of bilateral trade costs. Let $\tau_{ij}^k \equiv (t_{ij}^k)^{1-\sigma^k}$ the power transform of the bilateral trade cost factor. We construct τ_{ij}^k from the gravity coefficients and the proxy variables data as:

$$\hat{\tau}_{ij}^k = e^{\sum_{m=1}^4 \hat{\beta}_m^k \ln DIST_{ij} + \hat{\beta}_5^k BRDR_{ij} + \hat{\beta}_6^k LANG_{ij} + \hat{\beta}_7^k CLNY_{ij} + \hat{\beta}_8^k SMCTRY_{ij}}.$$

Here, the $\hat{\beta}$'s are the panel PPML gravity estimates. Where needed to get the levels of multilateral resistances, $\hat{\sigma}^k$ is the estimate of the elasticity of substitution obtained, as described in the data appendix, from the 3-digit HS indexes of Broda et al. (2006).³⁵

Theory implies that bilateral trade costs t_{ij}^k 's should always be greater than one. In less than one percent of the cases (mostly for the estimates of internal trade costs, \hat{t}_{ii}^k) our estimates are lower than one. To preserve the variability in the bilateral trade cost estimates, we divide each of them by $\hat{t}_{ij,min}^k$, where $\hat{t}_{ij,min}^k$ is the smallest estimate for a given class of commodities (usually the internal estimate for a small country). This transformation is inconsequential for our analysis since the full gravity system is homogeneous of degree zero in the set of gravity implied trade costs. Estimation can only identify relative trade costs.

The $\hat{\tau}$ s are used to solve the gravity system (5)-(6) for the power transforms of multilateral resistance terms for each country-commodity-year combination in the sample.³⁶ Overall, we find significant variation, within reasonable bounds, in the multilateral resistances across countries for a single product, and across commodity lines for a given country. For brevity and clarity of exposition, we construct and analyze aggregate indexes across all commodities for a given nation, and across all countries for a given commodity category. We use expenditure shares as weights in the aggregation of the inward multilateral resistances and output

³⁵Estimates of σ can be obtained directly as coefficients on bilateral tariffs in the gravity model. However, due to unavailability of bilateral tariff data for the period of investigation, we choose to use the elasticity indexes from Broda et al. (2006)

³⁶As discussed earlier, the gravity system solves for the multilateral resistances only up to a scale, therefore, we normalize all MR indexes by setting the US inward multilateral resistances equal to one.

shares in the aggregation of the outward counterparts.

Changing shares with constant bilateral trade costs drive changes in multilateral resistances. To describe the evolution of the multilateral resistances over time, we follow the procedure from Anderson and Yotov (2009) who adopt a time-invariant normalization to convert current prices to base year prices. Applied to our setting, the procedure is to convert US current inward multilateral resistance (chosen for normalization) to base year US inward multilateral resistance. Initially we calculate MR's for each commodity with $P_{USA}(t) = 1$ for each year t . This yields (for each commodity) a set $\{P_i(t), \Pi_i(t)\}$ for each region i and year t . Using output and expenditure shares, respectively as weights, we aggregate commodity level multilateral resistances to form country MR's. To convert them to intertemporally comparable values, we construct an inflator variable for US, drawn from country-level personal consumption expenditures (PCE) prices on durable and nondurable goods (but not services) for the period 1990-2002.³⁷ The inflator is equal to $\pi_{USA}(t) = PCE_{USA}(t)/PCE_{USA}(1990)$. The new set of 'time-consistent' MR's is $\{\pi_{USA}(t)P_i(t), (1/\pi_{USA}(t))\Pi_i(t)\}$. Conceptually, any country's inward MR is converted to a 1990 US dollars equivalent. For example, $P_i(t)/P_{USA}(t)$ is replaced by $P_i(t)/P_{USA}(1990)$. The scale of outward MR's is inversely related to the scaling of inward MR's due to the structure of the gravity system, so outward MR's are also interpreted as being in 1990 US dollars.

Deflated inward multilateral resistance (IMR) indexes are reported in Table 5. Column (1) reports IMR's by country for 1996, a midyear in our sample that is representative.³⁸ The IMR values vary across countries, and the pattern of IMR variation makes good intuitive sense. More 'remote' nations, geographically and in terms of industry concentration and economic development, face larger buyers' incidence. Thus developing countries and some former Soviet republics are consistently among the regions with highest buyers' incidence. In contrast, all developed countries are in the lower tail of the IMR distribution.

³⁷The PCE price index is constructed and maintained by the Bureau of Economic Analysis.

³⁸These numbers are the deflated yearly average inward multilateral resistances for each country across all goods, weighted by the national expenditure share on each commodity.

The numbers in column (2) of Table 5 summarize the IMR changes over the period 1990-2002 and are constructed using the chain procedure of Section 1.2. These indexes indicate that over time consumers in most countries (more than 80 percent of the nations in our sample) enjoyed a moderate decrease in the inward multilateral resistances. Consumers in Kuwait and Indonesia are the biggest winners. On the opposite side of the spectrum of IMR changes we find Russia, with an IMR increase of 14 percent, and another former Soviet republic, Azerbaijan. The estimates for these two nations are in accordance with the fact that they are among the countries with largest consumer price increases in the sample.³⁹ USA is the country with the third largest IMR increase in the sample.

IMR's vary across product lines for a single country. We aggregate across countries to portray the cross-commodity variation of the IMR's in Table 6. The numbers for each year and commodity are calculated as relative to the corresponding number for the United States. Thus, the indexes from column (1) of Table 6 suggest that the average consumer costs of Food, Wood, Paper, and Petroleum and Coal products are considerably higher in the rest of the world, as compared to the US, while the average costs of Apparel, Furniture, and Mineral Products are lower than in the US.

Estimates of the percentage changes in the IMR indexes, reported in column (2) of Table 6, show that, on average, the inward multilateral resistances have increased for most commodity categories (two thirds) in our sample. The increase varies by product line. At 12%, Food is the category for which consumers have suffered the largest IMR increase over the period 1990-2002. Furniture and Rubber and Plastic are the two other sectors with large IMR increase. Wood and Beverage and Tobacco are two of the categories with large IMR

³⁹In principle, IMR changes are comparable to average CPI changes. However, IMR's may only loosely track variations in consumer price indexes and any differences between the CPI's and the IMR's have a number of explanations. First, our IMR indexes are based on a manufacturing sample, excluding services, agriculture and mining. Second, the inward incidence of trade costs probably falls on intermediate goods users in a way that does not show up in measured prices. Third, the production weighted IMR's are not really conceptually comparable to the consumer price indexes of final goods baskets. Next, home bias in preferences may be indicated by our results. Home bias in preferences results in attributions to 'trade costs' that cannot show up in prices. Finally, the IMR's are no doubt subject to measurement error and are based on a CES model that itself may be mis-specified.

decrease. Petroleum and Coal is the category with largest IMR fall. This finding coincides with the stable oil prices of the 90's, followed by a fall in the early 2000's, and the fall in IMR's due to changing specialization patterns may be part of the explanation.⁴⁰

Outward multilateral resistance (OMR) indexes also vary across industries for a single country and across nations for a single sector. The pattern of variation makes good sense for the most part. Once again, to ease interpretation of our findings, we aggregate OMR's across commodities for each country and across countries for each commodity using commodity shipment shares as weights. The variation of the OMR's across countries is revealed in column (3) of Table 5, where we report deflated outward multilateral resistances for 1996. In column (4) of the table, we calculate the percentage change in the OMR's over the period 1990-2002 using the chain procedure of Section 1.2.

Several properties stand out. First, more remote regions (geographically and in terms of industry concentration and national specialization) face larger sellers' incidence. Thus, the vast majority of developing and third world countries are in the upper tail of the OMR distribution along with most of the former Soviet republics. In contrast, the majority of developed countries have low sellers' incidence. Also, our estimates capture the amazing growth and industrialization of "Asia's Four Little Dragons". Three of the five countries with lowest outward multilateral resistances in Table 5 are Hong Kong, Singapore and South Korea. The fourth Asian Tiger, Taiwan, most probably contributes significantly to the sixth place of China on the list, which it shares with Germany and Kuwait.

Second, OMR's are considerably larger than the IMR's. This result is in accordance with the findings of Anderson and Yotov (2009). To explain why the outward multilateral resistance exceeds its inward counterpart, they draw intuition from two propositions. According to Proposition 1, larger supply or net import shares (defined as the difference between expenditure shares and output shares) tend to reduce multilateral resistances in a special case. Building on the intuition from Proposition 1, in Proposition 2 they show that a greater

⁴⁰The oil price fall is also partly explained by a series of increases in OPEC quotas, increase in the Russian production, and a weakened US economy. Prices fell further immediately after the September 11 attacks.

dispersion of supply shares, which is an empirical regularity, drives average outward above average inward multilateral resistance. This pattern also plausibly reflects specialization, with causation running from multilateral resistances to supply (and demand) allocations.

The prediction of Proposition 1 holds up strikingly well in our OMR estimates, helping to explain some other results as well. Correlations between the OMR's and the output and net import shares at the product level, available upon request, reveal that the OMR's are significantly decreasing in output shares and decreasing in net import shares as well. The predictions of the proposition do not hold as well for the inward multilateral resistances. While we find a clear negative relationship between IMR's and supply shares, the correlation between the IMR's and the net import shares is mostly positive and significant.

Third, we find evidence of a decline over time in the OMR's for close to one-third of the nations in our sample and an increase in the seller's incidence for the rest of the countries. See column (4) of Table 5. As we employ panel gravity estimates to calculate the multilateral resistances, we interpret the changes in OMR's as driven by specialization that economizes on the trade cost bill for some nations but hurts others. (See Anderson and Yotov, 2009, for more development of the argument.) We see some countries with significant fall in OMRs as well as countries with large OMR increase.

Kuwait is the nation experiencing the largest OMR increase of more than 84 percent. The reason is the large increase in the incidence on the producers of Petroleum and Coal (Multilateral resistance and output changes for individual commodities are available upon request). Most of the oil producers in the world also suffered OMR increase, however, unlike other nations, the oil industry accounts for more than 85 percent of Kuwait's exports and for more than 50 percent of this country's GDP. A combination of the Iraqi invasion in 1990 along with the decrease in oil prices may explain this result. The fall in oil prices, of course, benefits oil consumers in Kuwait. In fact, the fall in the inward multilateral resistance outweighs the increase in the outward number for this particular country-industry combination, however the weight on oil consumption is much lower than the weight on oil

production for Kuwait as a whole. The situation is very similar for Oman, which is the nation with the second largest OMR increase of 34 percent in our sample.

It is also interesting to note that sellers in some republics from the former Soviet bloc (e.g., Russia, Armenia and Latvia) enjoy significant OMR decrease, while producers in other Soviet nations (e.g. Ukraine and Azerbaijan) suffer large increase in seller's incidence. Our explanation for these results is that after the collapse of communism, during the early '90s, most Soviet Union nations lost their guaranteed portion of the large Soviet market to more competitive producers, some of whom were former Soviet nations themselves.

The patterns of OMR variation across commodity categories and their change over time are revealed in columns (3)-(4) of Table 6. Column (3) reports deflated aggregates obtained with output shares used as weights. Furniture and Wood are always among the categories with highest outward trade costs at the country level, which translates into high aggregate indexes for these categories. Petroleum and Coal Products and Electrical Products are consistently among the sectors with lowest OMR indexes. Results from column (4) of Table 6 indicate that over the period 1990-2002 OMR's have fallen for more than half of the commodities in the sample. Food is the category for which producers have enjoyed the largest OMR fall of more than 12 percent. Beverage and Tobacco and Wood are two of the categories with largest OMR increase. Petroleum and Coal is the outlier with OMR increase of 80 percent.

Comparison between the changes in the incidence on consumers and producers at the product level reveals two interesting patterns. First, any IMR fall is inevitably accompanied by an OMR increase. And, second, the changes in the corresponding inward and outward multilateral resistances for each category are almost equal in absolute value. This suggests that the gains or losses for buyers(sellers) of each good are at the expense of producers(consumers) of these products. This result is also captured by the real output numbers reported in column (7) of the table, which we discuss shortly.

The MR characteristics are in sharp contrast to those of Laspeyres trade cost (LTC)

indexes. Share-weighted Laspeyres indexes of bilateral trade costs for each country and year are constructed as follows. The outward index is calculated as $\sum_k \hat{T}_i^k Y_i^k / \sum_k Y_i^k$, where $\hat{T}_i^k \equiv \sum_j \hat{t}_{ij}^k X_{ij}^k / Y_i^k$. The inward counterpart calculation is $\sum_k \hat{T}_j^k E_j^k / \sum_k E_j^k$, where $\hat{T}_j^k \equiv \sum_i \hat{t}_{ij}^k X_{ij}^k / E_j^k$. The inward and the outward LTC's (available on request) are almost identical and the same is true for their evolution over time. There is a significant positive correlation between the OMR's and both outward and inward LTC's. In contrast, there is a weak negative correlation between inward multilateral resistance and either of the LTC measures. Despite the high correlation of the OMR's and the LTC's, the magnitudes are different. For example, the outward LTC's range from 1.54 to 3.72 while the OMR's range from 1.95 to 6.17. This difference has important resource allocation and welfare implications.

An even more important difference between LTC's and multilateral resistances is that LTC's are flat over time. Use of Laspeyres indexes to portray the evolution of trade costs completely misses the pro- and anti-globalizing forces of specialization revealed by the multilateral resistance indexes. While the latter require reliance on a special and restrictive theory of structural gravity, they at least attempt to measure the meaningful concept of incidence, and our results show that in practice the differences between Laspeyres indexes and multilateral resistance are significant.

4.3 Constructed Home Bias

Constructed Home Bias (CHB) is calculated with (7) using the power transforms of estimated t 's and multilateral resistances for each commodity and country. In practice t_{ii}^k is the estimated internal trade cost for country i and commodity k relative to the smallest internal trade cost for commodity k across all countries and regions. It is important to note that the normalization used to solve the gravity system for the (power transforms of) multilateral resistances does not play any role in the CHB construction: CHB is independent of the normalization, and of elasticity of substitution estimates because it is constructed using the $1 - \sigma_k$ power transforms of t 's, Π 's and P 's.

Aggregated country level CHB indexes,⁴¹ are obtained as weighted averages across commodity level CHB values. Recalling that CHB is interpreted as the predicted value of internal trade relative to the theoretical value of internal trade in a frictionless world, the aggregate CHB for country or region i should be the ratio of predicted internal total trade $\sum_k \hat{X}_{ii}^k$ to frictionless internal total trade $\sum_k Y_i^k E_i^k / Y^k$. This can be obtained from (7) as:

$$CHB_i = \sum_k \left(\frac{t_{ii}^k}{\Pi_i^k P_i^k} \right)^{1-\sigma_k} \frac{Y_i^k E_i^k / Y^k}{\sum_k Y_i^k E_i^k / Y^k},$$

the weighted average of commodity CHB's, where the weights are equal to the frictionless internal trade shares.

Column (5) of Table 5 portrays the cross-national variation of CHB in 1996, which is representative of our findings across the whole period 1990-2002. Three properties stand out. First, most of the CHB values are large. There is a massive home bias in trade flows. Second, there is wide variability in CHB. Third, CHB is larger for the less developed and the smaller countries, and lower for the more developed and the industrialized nations. Thus, in each year, the United States (USA), Japan (JPN), and Germany (DEU) are consistently the three countries with the lowest constructed home bias indexes. On the opposite side of the CHB spectrum are developing and small countries such as Mozambique (MOZ), Trinidad and Tobago (TTO) and Senegal (SEN), as are most of the former Soviet republics.

The CHB changes over the period 1990-2002 are entirely due to the general equilibrium effect of changes in production and expenditure shares on multilateral resistance. A fall in CHB's implies 'globalization', a fall in external trade costs relative to internal trade costs. The fall is not due to the usual understanding of globalization because the fitted trade costs t_{ij} 's (including the internal fitted values t_{ii} 's) are constant over time by definition, as we employ the panel (time-invariant) gravity estimates to construct them. Intriguingly, globalization creates losers with rising CHB as well as winners with falling CHB.⁴²

⁴¹CHB indexes at the product level for each country are available upon request.

⁴²To assess the relative importance of specialization vs. changes in bilateral trade costs, we construct an alternative CHB measure, where we employ the yearly gravity estimates to calculate fitted trade costs.

Column (6) of Table 5 reports percentage changes in CHB for each country and region in our sample. Our estimates indicate that from 1990 to 2002, CHB falls for more than half of the countries while rising for the rest. The pattern is mostly explained by a parallel association between market share and outward multilateral resistance. Slower than average growth implies smaller market shares that are associated in the cross section with higher outward multilateral resistance. The more developed and industrialized economies, which in the 90's are already pretty well set in their specialization patterns, do not experience large CHB changes. Thus the United States, Germany, Great Britain, and France are in the middle of the distribution of CHB changes. Notably, US experiences a moderate fall in CHB. Japan, in contrast, experiences a large CHB increase. This is likely due to its lost decade of slow growth in the 90s.

The newly liberalizing economies, which are changing their economic conditions and patterns of specialization rapidly are as expected at the upper tail of the distribution of CHB changes. For example, Mexico and China are among the nations experiencing large CHB falls. Specialization by these two nations, during the period of investigation, was stimulated by their entry into major trade agreements with the US.⁴³ Some of the smaller European economies, such as Portugal and Greece, that have not gone through serious economic changes during the period 1990-2002, experience an increase in CHB. The explanation could be that during the 90's, these nations faced a tough competition for EU markets and resources from the newly accepted members. Finally, the big changes in former Soviet bloc trade had different effects on the CHB for the Soviet republics. Most of them suffered a significant CHB increase. Notably, the three countries with largest CHB increase are the Kyrgyz Republic, Ukraine and Azerbaijan. However, some former Soviet nations (e.g., Estonia, Latvia and Armenia) enjoyed CHB fall.

Comparison between the CHB changes obtained with the panel and the yearly gravity estimates (available upon request) reveal that they are almost identical. Thus, the CHB fall is indeed due to the general equilibrium effect of changes in production and expenditure shares on the multilateral resistances, and the usual forces of globalization have played a small role for the CHB changes during 1990-2002.

⁴³In addition, during the 90s, Mexico was heavily involved in the integration processes taking place in Latin America, and toward the end of the period the country also signed an FTA with the European Union.

CHB's vary across product lines for a single country. The patterns of CHB variation across commodity categories and their change over time are revealed in columns (5) and (6) of Table 6. Notably, we find that product-level CHB indexes are relatively small and much more homogeneous as compared to their country-level counterparts. The explanation for the small magnitude is that larger and more developed countries, that have very low CHB values, are given higher weight (due to their size) in obtaining the aggregate CHB indexes for each category. Even though CHB variation across product lines is not large, it makes intuitive sense for the most part. For example, we estimate large home biases for Food and Beverage and Tobacco, which we believe are demand-driven, and for Petroleum and Coal and Mineral Products, which we explain with the nature of production and supply.⁴⁴ The low CHB values for Leather and Transportation are also intuitive and can be explained with clear world specialization patterns in these manufacturing sectors.

4.4 TFP, Incidence and Real Output

Changes in the incidence of trade costs (globalization) impact real output like TFP changes. The real output changes in the last column of Table 5, are constructed using the chain procedure of Section 1.2. As discussed earlier, buyers in most countries have enjoyed decreasing inward multilateral resistances (column 2), while sellers in about two thirds of the nations have suffered an increasing incidence of trade costs (column 4). The changes in real output, in column 7, suggest that a bit more than half the world's countries experience rising real output while the remainder of countries experience falling real output. Globalization as specialization generates winners and losers, tending toward a zero sum in our sample. It is important to note that our results for real output changes are independent of (i) the normalization used to calculate the multilateral resistances, and (ii) the choice of a price

⁴⁴In particular, even though Petroleum and Coal and Mineral Products are natural resource sectors and one may expect low home biases for these categories, it should be remembered that our data covers trade and production of manufactured products, which often are produced domestically from crude natural resources that are imported, however our data does not cover natural resource trade flows. This also explains the large gravity estimates of the SMCTRY coefficients, capturing internal trade, for Petroleum and Coal, Minerals, and Wood.

deflator (if any) used to intertemporally link the multilateral resistances. In contrast, the results *are* sensitive to the choice of elasticity of substitution in each sector, and the division of gains/losses between buyers and sellers *does* depend on the external price deflator.

The pattern of real output changes makes intuitive sense for the most part. In the cross section, and over time, sellers' incidence tends to fall with increases in output shares.⁴⁵ Thus, nations that have been heavily involved in trade (and wider economic) liberalization during the 90s, such as China and Mexico, are among the countries with largest real output gains.⁴⁶ Disaggregated real output changes (available upon request) reveal that these nations are consistently among the countries with largest real output gains at the commodity level.

Most of the countries that suffer large real output decline during the 90s are developed nations, economies in transition, and members of the former Soviet bloc. In the case of the latter (see Russia for example) producers often enjoy significant decrease in outward multilateral resistance, however, the loss for consumers is even larger. These findings are supported at the commodity level as well. Along with the developing economies and the economies in transition, some developed nations, led by Japan, also experienced large real output loss. The explanation is that Japan suffered a lost decade of slow growth in the 90s. Most of the other developed nations are in the middle of the real output changes distribution.

For some nations, the real output effect of globalization is quite heterogeneous across sectors. For example, Brazil enjoyed the third largest real output gain (after China and Hong Kong, but in front of Italy) for leather products in the world. This is consistent with the fact that Brazil is one of the world's largest leather producers and it gained significantly from the geographical redistribution of the leather industry during the early 90s. More interestingly, Brazil is the leader in real output gains in the Petroleum and Coal industry. Brazilian consumers benefitted from falling oil prices during the 90s. Brazilian oil producers

⁴⁵See Anderson and Yotov (2009) for more evidence and some theoretical insight.

⁴⁶Venezuela is another example of a country that liberalized trade intensively during the 90s. Moreover, oil accounts for only one third of Venezuela's GDP, while manufacturing, which accounts for about one fifth of GDP, has been growing steadily at very high rates. These characteristics explain Venezuela's high real output benefit from the incidence of TFP in distribution.

however, were some of the few in the world that actually enjoyed a fall in outward multilateral resistance. A possible explanation is the opening of the oil sector in this country to private and foreign investors during the late 90s, when Brazil began establishing itself as one of the big players in the oil industry.

While globalization as specialization generates clear winners and losers at the country-level, our estimates reveal no significant real output changes for the world economy at the product-level over the period 1990-2002. See column (7) of Table 6. The overall real output effect for all manufacturing in the world economy is 0.3%. In principle, the shifts in output and expenditure shares could significantly raise this measure of world efficiency, as on a smaller scale Anderson and Yotov argued was the case for Canada's provinces, due to expenditure on average rising where inward trade costs are relatively low and similarly supply rising where outward trade costs are relatively low.⁴⁷

Openness is positively associated with growth via the globalization as specialization channel. Changes in CHB and changes in the incidence of TFP have a correlation coefficient varying between -0.3 and -0.4 , depending on the approach used in the calculation of real output changes.⁴⁸

4.5 Testing Structural Gravity

Structural gravity implies that the sum of the origin (exporter) and destination (importer) country fixed effects $\eta_{i,t}^k + \theta_{j,t}^k$ from equation (12) should be equal to $\ln [E_j^k P_j^{k\sigma_k-1} Y_i^k \Pi_i^{k\sigma_k-1} / Y^k]$.

The constant term Y^k implies that the origin and destination fixed effects are not separately

⁴⁷Totally differentiate (5)-(6), multiply by $s_i \equiv Y_i/Y$ and $b_j \equiv E_j/Y$ respectively and sum over countries. Rearranging the results: $\sum_i (s_i + \sum_j w_{ij}) \widehat{\Pi}_i + \sum_j (b_j + \sum_i w_{ij}) \widehat{P}_j = \frac{1}{1-\sigma} \left(\sum_{i,j} w_{ij} \widehat{b}_j + \sum_{i,j} w_{ij} \widehat{s}_i \right)$, where $w_{ij} = s_i b_j (t_{ij}/\Pi_i P_j)^{1-\sigma}$ and $\sum_{i,j} w_{ij} = 1$. In the frictionless economy, the right hand side is equal to zero because the sum of shares is equal to 1. Elsewhere, the right hand side is negative as b 's tend on average to rise where the composite trade friction term is large (i.e., $t_{ij}/\Pi_i P_j$ is small), and as s 's tend on average to rise where the composite trade friction term is large ($t_{ij}/\Pi_i P_j$ is small).

⁴⁸The correlation indexes obtained with the chain-type output numbers are larger. Furthermore, if we eliminate the outliers with CHB indexes above 1000, the correlation between the changes in CHB and the changes in the incidence of TFP varies between -0.4 and -0.5 .

identified.⁴⁹

This prediction of structural gravity can in principle be tested, allowing for the constant term, with the regression:

$$\hat{\eta}_{i,t}^k + \hat{\theta}_{j,t}^k = \gamma_0^k + \gamma_1^{k,t} \ln [E_{j,t}^k P_{j,t}^{k \sigma_k - 1} Y_{i,t}^k \Pi_{i,t}^{k \sigma_k - 1}] + e_{ij,t}^k \quad (13)$$

for each k and t . Here $e_{ij,t}^k$ is a random error term, $\hat{\eta}_{i,t}^k$ and $\hat{\theta}_{j,t}^k$ are the estimates of the exporter and importer fixed effects⁵⁰ for the indexed country in commodity class k at time t (measured as deviations from the corresponding value for US, which is the excluded country in our first-stage gravity estimations), $(P_{j,t}^k)^{1-\sigma_k}$ and $(\Pi_{i,t}^k)^{1-\sigma_k}$ are calculated as above, while the E 's and Y 's are data. Theory predicts $\gamma_1^{k,t} = 1$ while $\gamma_0^k = \ln Y_t^k$ plus any systematic commodity/time-specific measurement error.

Our estimated γ_1 's cluster very close to 1 with an overall estimate of 0.96. In an economic sense structural gravity comes remarkably close, though a standard F-test rejects the null hypothesis $\gamma_1 = 1$. Notably, time effects are insignificant, meaning that the structural gravity term (the composite plus the product-year fixed effects) soaks up all the time variation in the model. The top panel of Table 7, labeled Aggregate Fixed Effects, presents the results of (13) pooled across sectors (with sector fixed effects). The column headed Panel also pools across time.⁵¹ Decomposing by sectors, some γ_1 's are more different from 1 while others are not statistically significantly different from 1. Without Textiles and Apparel, where the un-modeled MFA is at work, the coefficient rises closer to 1 and the F-statistic falls.⁵²

Another use of model (13) highlights the relative importance of the structural gravity term. Estimating with just that term, then adding the block of product-year fixed effects and

⁴⁹Information on Y^k can be utilized for identification but it may be problematic due to measurement error.

⁵⁰To take advantage of the additional information contained in the standard errors of the country-specific, directional fixed effects, we estimate (13) using weighted ordinary least squares with weights equal to the inverse squared standard errors of the sum of the fixed effect estimates. The intuition being that more precise estimates should be given higher weights in the estimations.

⁵¹Yearly estimates are obtained with industry fixed effects, and product-year dummies are employed in the panel estimations.

⁵²We also experiment by removing Petroleum and Coal from the sample. Results are not sensitive to such specification.

then finally a block of country fixed effects, all blocks are statistically significant using the standard Wald test while structural gravity explains 60% of the variance, the product-year fixed effects add another 34% and the country fixed effects add 1%. Table 7 presents the results of a number of eclectic regressions that give an idea of the relative importance of the various components of structural gravity. These results are useful as descriptive statistics but they ignore measurement error bias.⁵³

An alternative procedure based on 7 avoids the problem of measurement error. It similarly demonstrates the relative unimportance of deviations from structural gravity due to unmodeled country fixed effects. Impose $\gamma_1^{k,t} = 1$ and solve for

$$\hat{\eta}_{i,t}^k + \hat{\theta}_{j,t}^k - \ln [E_{j,t}^k P_{j,t}^{k \sigma_k - 1} Y_{i,t}^k \Pi_{i,t}^{k \sigma_k - 1}] = \gamma_0^k(t) + e_{ij,t}^k.$$

The left hand side is observable, and can be regressed on a set of sector-time fixed effects and country fixed effects in a panel structure:⁵⁴

$$\hat{\eta}_{i,t}^k + \hat{\theta}_{j,t}^k - \ln [E_{j,t}^k P_{j,t}^{k \sigma_k - 1} Y_{i,t}^k \Pi_{i,t}^{k \sigma_k - 1}] = \alpha_0 + \psi_t^k + \phi_i + e_{ij,t}^k \quad (14)$$

Sector-time fixed effects reflect Y_t^k in structural gravity. Country fixed effects surely reflect country-specific border barriers not modeled in (12) due to lack of observations. Thus any values of the coefficients could be consistent with structural gravity. But country fixed effects could alternatively indicate deviations from the structural gravity model such as activity elasticities not equal to one. We test sensitivity to alternative implications of country fixed effects by showing that structural gravity does quite well even under the no country fixed effects ($\phi_i = 0$) specification.

Figure 1 illustrates the results. The x-axis shows the dependent variable of (14) and the

⁵³Since the multilateral resistances are constructed using the first stage gravity coefficients, they surely are measured with error that is correlated with the e 's. In principle, the measurement error could be treated.

⁵⁴Since the $\hat{\eta}_{i,t}^k + \hat{\theta}_{j,t}^k$ variables are estimated as deviations from the US, the composite variable $\ln [E_j^k P_j^{k \sigma_k - 1} Y_i^k \Pi_i^{k \sigma_k - 1}]$ is also constructed as a deviation from the US value.

y-axis shows the fitted residual values $\widehat{e}_{ij,t}^k$ of (14). If neither sector-time nor country fixed effects mattered, the points would lie on the 45 degree line. Instead, the sector-time fixed effects control for systematic variation. Dispersion is indicated by the 95% confidence band about the line. The line labeled “Fitted Values No Country FEs” gives the fitted values of (14) estimated subject to $\phi_i = 0$.⁵⁵ The statistical test of country fixed effects rejects the null hypothesis, but the lines are close together in the sense that the “No Country FEs” line is well inside the 95% confidence band for the All FEs specification for most of the relevant range.⁵⁶ The picture suggests that the restrictions of structural gravity come close to being satisfied by the data even if unmodeled country-specific characteristics include components outside the model. A further consistency check follows because the estimated $\widehat{\psi}_t^k + \widehat{\phi}_i$ values can be rescaled as factors that shift trade flows of the gravity equation in levels, obtained by exponentiating. These range from around 0.3 to 2.3, plausibly associated with sector fixed effects.⁵⁷

An eclectic approach allows for directional country fixed effects not implied by structural gravity:

$$\hat{\theta}_{j,t}^k = \alpha_0^k + \alpha_2^k \ln(P_{j,t}^k)^{\sigma_k-1} + \alpha_3^k \ln E_{j,t}^k + v_{j,t}^k \quad (15)$$

for the destination country, and

$$\hat{\eta}_{i,t}^k = \beta_0^k + \beta_2^k \ln(\Pi_{i,t}^k)^{\sigma_k-1} + \beta_3^k \ln Y_{i,t}^k + u_{i,t}^k \quad (16)$$

⁵⁵For visual clarity, the data range is truncated to exclude an outlying 0.18% of dependent variable observations.

⁵⁶About 1/4 of country fixed effects are not statistically significant, although the F-test for joint significance rejects the null hypothesis for country-specific fixed effects. We also experiment by breaking the sector-time dummies into separate year and product fixed effects to find that none of the year dummies are economically significant, and the three year coefficients that are statistically significant (1991, 1993 and 2001) are only marginally so. Full details are available on request.

⁵⁷The time component is unimportant in our data. The range of the fitted values is comparable to the range of values implied by the total shipments data $Y^k / [\sum_k Y^k / N]$ where N is the number of sectors. This is (0.07, 2.36) and is stable over time. There is no need for the two ranges to match to be consistent with structural gravity, because of the influence of country effects on the fitted values and because the structural gravity model can allow for measurement error such that the constant term need not equal the mean shipment value.

for the source country. The eclectic form (15)-(16) produces results that deviate more (as compared to (13)) from the strict structural gravity model. See the panels labeled Inward Effects and Outward Effects in Table 7 for the results pooled across sectors. Both the strict and eclectic versions of gravity indicate that the structural model variables account well for much of the variation in the directional fixed effects.

The results give useful clues for amending the theory. Most notably, some sectors are less well described by structural gravity than the others, especially those for Textiles and Apparel where the Multi-Fibre Arrangement is at work. Dropping these sectors moves γ_1 closer to 1. A better approach, beyond the scope of this study, is to specify bilateral trade costs for these sectors to capture the effect of the MFA.

The earlier gravity literature utilized GDP's of origin and destination countries and often found elasticities that differed from 1. Previous estimates are dubious for three reasons. First, aggregate gravity suffers from aggregation bias (Anderson and van Wincoop, 2004). Second, the appropriate activity variables are for total shipments, not a value added concept like GDP. Third, gravity models without controls for multilateral resistance have omitted variable bias (Anderson and van Wincoop, 2003).

4.6 Aggregation Bias

Large aggregation bias is revealed comparing our results with gravity coefficients estimated on aggregates of the 18 industries. Distance elasticities and border effects from aggregate data are reduced by a third or more in absolute value. More important, there is downward bias in CHB. The bias is skewed toward the less developed countries and close to zero for the most developed countries.

CHB changes and real output changes from aggregate data are reduced in average absolute magnitude, implying dispersion is reduced. The good performance of the gravity model on disaggregated data is notable in relation to the earlier gravity literature, which encountered poorer performance with disaggregated estimation. We conclude that future gravity

modeling should concentrate on disaggregated estimation.

5 Conclusion

Specialization acting on the incidence of trade costs is revealed in this paper to be a powerful force moving the world's economies. The results show that more than half of the 76 countries experience significant declines in Constructed Home Bias while the remainder experience rising CHB. Changes in buyers' and sellers' incidence raise real output of more than half the countries while lowering real output of the remainder. At the extremes, the changes in CHB and the real output effects of incidence changes are big.

The disaggregated structural gravity model is revealed as remarkably successful in fitting the manufacturing data. Despite this, our methods uncover remaining anomalies that point toward refinement of the model, taking us beyond the scope of this paper. Future work should address the impact of measured border restrictions and proxies for non-border variables that act differentially on international trade, confronting the issues of endogeneity that arise. Future work should also include development of data that would permit extending the coverage of structural gravity estimation to disaggregated trade flows in non-manufacturing sectors. Parallel work with regional trade flow data (Anderson and Yotov, 2009) reveals large within-country differences in the implications of specialization for one country (Canada). Future research should include improvements in regional trade flow data for other countries as an aid to understanding the sharp differences between regions that emerge with globalization.

Columns (1) and (3) of this table report deflated IMR and OMR levels, respectively by country for 1996. IMR (OMR) indexes are obtained from the corresponding individual commodity category values with expenditure (output) shares used as weights. IMR and OMR changes over the period 1990-2002, constructed using the chain procedure described in the text, are reported in columns (2) and (4). CHB levels and changes by country are presented in columns (5) and (6). Column (7) reports real output changes by country over the period 1990-2002.

Standard errors in parentheses. + $p < 0.10$, * $p < .05$, ** $p < .01$. The yearly estimates are obtained with product fixed effects. The panel estimates are obtained with product-year fixed effects. Fixed effects estimates are omitted for brevity. The estimator is weighted least squares. See text for details.

Appendix A: Technical Appendix

Normalization

Normalization must ultimately be consistent with both the gravity module and the general equilibrium superstructure. Note that the CES price index is given by

$$P_j^{1-\sigma} = \sum_i (\beta_i p_i^*)^{1-\sigma} t_{ij}^{1-\sigma}. \quad (17)$$

Imposing $P_j = 1$ implies, for given (estimated) t_{ij} 's, a normalization on the unknown $\beta_i p_i^*$'s. Then $(\beta_i p_i^*)^{1-\sigma}$ can be solved for using the CES demand for each good i in location j :

$$X_{ij}/E_j = (\beta_i p_i^*)^{1-\sigma} t_{ij}^{1-\sigma}, \forall i.$$

The resulting $(\beta_i p_i^*)^{1-\sigma}$'s can in principle be used to check that the theoretical normalization of the Π 's is met by the Π 's calculated with the actual procedure: set $P_j = 1$ and drop the j th CES price index equation $P_j^{1-\sigma} = \sum_i (t_{ij}/\Pi_i)^{1-\sigma} Y_i/Y$ from the MR system. Because the multilateral resistance system is constructed and solved using $Y_i/Y = (\beta_i p_i^* \Pi_i t_{ij})^{1-\sigma}$ it is automatically consistent with the theoretical normalization.

Some other choice such as $P_{j+1} = 1$ will change the solution to multilateral resistances but with no implications for allocation. Demand system estimation can only ever identify the β 's up to a scalar, so picking some $P_j = 1$ is effectively normalizing the estimated coefficients $\{\beta_i\}$.

TFP and Real Output

The conceptual economic foundation for the real output calculations is the expenditure function for a representative consumer $e(P_f, u)$ where P_f denotes the vector of final goods prices to the consumer and u denotes real income; and the maximum value GDP function for the supply side of the economy $g(\Pi, P_m, v)$ where Π denotes the vector of seller price *deflators*

(the factory gate price is inversely related to Π), P_m denotes the vector of intermediate input prices to buyers and v denotes the vector of primary factors. For notational ease the country subscript is suppressed.

Conceptually sound index numbers use the distance function to aggregate vectors of price changes into scalar indexes so as to be consistent with economically meaningful objectives. It is helpful as a preliminary step to illustrate with the ‘true cost of living’ index. The goal is to define a real-income (utility) equivalent index of a ‘new’ price vector P^t with respect to an ‘old’ reference price vector P^0 . There are two consistent alternatives:

$$C(P^t, P^0, u^0) = C : e(C \cdot P^t, u^0) = e(P^0, u^0) \quad (18)$$

and

$$E(P^t, P^0, u^t) = E : e(\cdot P^t, u^t) = e(D \cdot p^0, u^t). \quad (19)$$

(18) is a compensating variation index that deflates the new price vector so as to reduce real income to the old level u^0 , all while maintaining expenditure at the old level. (19) is an equivalent variation measure that deflates the new price vector so as to deliver the new level of utility if the economy faced the old vector of prices, all while maintaining expenditure at the new level. Notice that with a set of ‘new’ prices in a time series, (19) has changing real income u^t while (18) maintains real income at u^0 .

We develop the equivalent variation indexes below, and in the text we report only the equivalent variation measures. In practice the difference between them in our application involves whether we deflate the inward Multilateral Resistance of our numeraire country with its measured CPI. The deflated and un-deflated series are very highly correlated in our calculations. Impose the budget constraint in the new situation:

$$e(P^t, u^t) = g^t. \quad (20)$$

Here, g^t is exogenous but eventually it is equated with GDP. Differentiate (19) totally using (20) and solve for

$$\widehat{D} = \frac{e_u^0}{e_u^t} \frac{e_P^t \cdot P^t}{e_P^0 \cdot P^0 D} \sum_k \frac{e_{P_k^t}^t P_k^t}{e_P^t \cdot P^t} \widehat{P}_k^t - \frac{e_u^0}{e_u^t} \frac{g^t}{e_P^0 \cdot P^0 D} \widehat{g}^t. \quad (21)$$

If the price vector includes all the prices then by construction $e_P^t \cdot P^t = e_P^0 \cdot P^0 D$ and $e_u^0(D \cdot P^0, u^t) = e_u^t$. The same simplifying cancellation of terms occurs if the price vector P enters the expenditure function separably: $e(P, q, u) = f(\phi(P), q, u)$ where $\phi(P)$ is a concave homogeneous of degree one function that naturally aggregates the prices in P and f_ϕ is the natural quantity aggregate while q is another price vector. To see that the same simplification goes through, note that in the separable case, $e_P^t(P^t, q^t, u^t) \cdot P^t = e_\phi^t \phi_P^t \cdot P^t = e_\phi^t \phi^t$ and $\phi^t = D\phi^0$. Then

$$\widehat{D} = \sum_k \frac{e_{P_k^t}^t P_k^t}{e_P^t \cdot P^t} \widehat{P}_k^t - \widehat{g}^t. \quad (22)$$

(22) gives the basic logic for the constructed real output index in the text from the deflated multilateral resistances. The numeraire country has its inward multilateral resistance set equal to one in our calculations for each year. The time series of multilateral resistance are linked by inflating the inward multilateral resistances for the numeraire country by its CPI for each year and thus inflating each other country's inward multilateral resistances by the same factor, corresponding the each \widehat{P}_k^t for each country (country indexes being omitted here for simplicity). The logic of the gravity model equilibrium requires *deflating* each country's outward multilateral resistance by the same factor.

The real output index G is implicitly defined by

$$e(G^t P_f^0, q^t, u^t) - g(G^t \Pi^0, G^t P_m^0, q^t, v^t) = e(P_f^t, q^t, u^t) - g(\Pi^t, P_m^t, q^t, v^t). \quad (23)$$

Here, $g(\cdot)$ is the GDP function, P_f denotes final goods prices to consumers, P_m denotes intermediate goods prices to producers and Π is inversely related to the output prices received

by producers at the factory gate. The superscript 0 denotes the base year set of multilateral resistances, real incomes and primary factors and t indicates some other year. q^t denotes the set of other prices in the economy not captured by the incidence of trade cost analysis. Apply Shephard's and Hotelling's Lemmas, and impose separability of preferences with respect to the partition between goods with prices P and other goods combined with separability in the technology that similarly permits natural aggregation of goods with sellers incidence Π and buyers' incidence P_m . Then the local rate of change of G is as given in (8). This equation can be re-written using logs, replacing \hat{x} with $d \ln x$. If the functional forms $e(\cdot), g(\cdot)$ were known, the log differential equation could be integrated to obtain the discrete change in log G , exponentiating to obtain the Divisia index of G . The functional forms of $e(\cdot), g(\cdot)$ being unknown, the observed shares at the various points on the 12 year interval can be used, raising the issue of the best approximation. The Tornqvist approximation that averages adjacent year's shares has good properties when shares change relatively smoothly. See Diewert (2008) for discussion.

The multilateral resistance changes being used in the text cover only a small portion of the economy. If the part not covered experienced equal change in buyers' and sellers' incidence then our real output index would equal a real GDP index. With no change elsewhere the real GDP effect of the rate of change of the real output we report would be equal to the share of the outputs we include in GDP times the rate of change of the real output index (23). Since this share is not observable (our calculations are based on total shipments, not the value-added that would be needed to construct GDP shares), we report only our 'real output' index calculated with the logic of (23) using total shipment shares on the supply side and total expenditure shares on the demand side (final and intermediate purchases combined).

This development of the logic of our real output suggests that our estimates of G changes are sensible aggregates of the commodity level changes in incidence to buyers and sellers. The discussion indicates how much more work would need to be done to pin down the link from our measures to real GDP itself.

Appendix B: Data Appendix

The study covers 76 trading partners.⁵⁸ Bilateral trade flows, measured in thousands of current US dollars, are from CEPII’s *Trade, Production and Bilateral Protection Database*⁵⁹ (TradeProd) and the United Nation Statistical Division’s COMTRADE Database.⁶⁰ TradeProd database is the primary source. The reason is that TradeProd is based on CEPII’s *Base pour l’Analyse du Commerce International* (BACI), which implements a consistent procedure for mapping the CIF (cost, insurance and freight) values reported by the importers in COMTRADE to the FOB (free on board) values reported by the exporters in COMTRADE.⁶¹ To further increase the number of non-missing bilateral trade values, we add the mean of the bilateral trade flows from COMTRADE.⁶² The final issue with the trade data is that in some instances the reported value of output is smaller than the value of exports. These observations were dropped from the gravity estimations sample.

Industrial production data comes from two sources. The primary source is the United Nations’ UNIDO Industrial Statistics database, which reports industry level output data at the 3 and 4-digit level of ISIC Code (Revisions 2 and 3). In addition to UNIDO, we use CEPII’s TradeProd database,⁶³ as a secondary source.⁶⁴ 10.8 percent of the original data were missing after combining the two data sets. As output data are crucial for the

⁵⁸Argentina, Armenia, Australia, Austria, Azerbaijan, Bulgaria, Belgium-Luxembourg, Bolivia, Brazil, Canada, Chile, China, Colombia, Costa Rica, Cyprus, Czech Republic, Germany, Denmark, Ecuador, Egypt, Spain, Estonia, Finland, France, United Kingdom, Greece, Guatemala, Hong Kong, China, Hungary, Indonesia, India, Ireland, Iran, Italy, Jordan, Japan, Kazakhstan, Kenya, Kyrgyz Republic, Korea, Kuwait, Sri Lanka, Lithuania, Latvia, Morocco, Moldova, Mexico, Macedonia, Malta, Mongolia, Mozambique, Mauritius, Malaysia, Netherlands, Norway, Oman, Panama, Philippines, Poland, Portugal, Romania, Russian Federation, Senegal, Singapore, El Salvador, Slovak Republic, Slovenia, Sweden, Trinidad and Tobago, Turkey, Tanzania, Ukraine, Uruguay, United States, Venezuela, South Africa.

⁵⁹For details regarding database see Mayer, Paillacar and Zignago (2008).

⁶⁰We access COMTRADE through the World Integrated Trade Solution (WITS) software, <http://wits.worldbank.org/witsweb/>.

⁶¹As noted in Anderson and Yotov (2009), in principle, gravity theory calls for valuation of exports at delivered prices. In practice, valuation of exports FOB avoids measurement error arising from poor quality transport cost data. For details regarding BACI see Gaulier and Zignago (2008).

⁶²We also experiment by just using the export data from COMTRADE and then assigning missing trade values to the observations when only data on imports are available. Estimation results are very similar.

⁶³TradeProd uses the OECD STAN Industrial Database as well as UNIDO’s IndStat Database.

⁶⁴We experiment with two output variables, based on the main data source, to obtain identical results.

calculation of the multilateral resistance indexes, we construct the missing values. First, we interpolate the data to decrease the missing values to 8.6 percent.⁶⁵ Then, we extrapolate the rest of the missing values using GDP deflator data, which comes from the World Bank’s World Development Indicators (WDI) Database.⁶⁶

To construct expenditures, we add the value of total imports from all partners to the value of output and subtract the value of total exports for each country and each industry. The main source of data on total sectoral imports and exports is TradeProd. Once again, we use COMTRADE as a secondary trade data source. 4.7 percent of the expenditures were missing.⁶⁷ To construct the missing values, first, we interpolate the data, then, we extrapolate the rest using CPI data from the WDI Database.⁶⁸

In order to calculate the multilateral resistance indexes, we need data on elasticities of substitution at the commodity level. These data are obtained from Broda et al (2006), who estimate and report 3-digit HS indexes for 73 countries for the period 1994-2003. This period almost coincides with the period of investigation in our study. We use imports as weights to aggregate the original indexes to the level of commodity aggregation in our study. In addition, as some of the original numbers seem implausible,⁶⁹ we bound the originals in the interval $[4,12]$ before aggregation. We view the aggregated elasticity indexes as plausible. More homogeneous categories (e.g. Wood and Paper products) have higher values, while less homogeneous categories (e.g. Furniture and Transportation products) have lower numbers.

We experiment with several distance variables based on different approaches in the calculation of internal as well as bilateral distances.⁷⁰ Provided that our results are robust to

⁶⁵Most of the missing observations are for the early years in the sample (1990-1993) and for the former Soviet republics (e.g. Armenia, Estonia, Lithuania, etc.), which declared independence during the early 90s.

⁶⁶GDP deflator data were not available for Belgium-Luxembourg (BLX). We use Belgium’s GDP deflator data to proxy for BLX.

⁶⁷0.29 percent (91 out of 30,888 observations) of the expenditures were negative. We replaced these observations to missing. Once again, most of the missing observations are for the early years in the sample (1990-1993) and for the former Soviet republics, which declared independence during the early 90s.

⁶⁸CPI data were not available for Belgium-Luxembourg (BLX). We used Belgium’s CPI to proxy for BLX.

⁶⁹For example, the elasticity estimate for the 3-digit HS commodity category 680, which includes Articles of asphalt, Panels, boards, tiles, blocks, Friction materials etc. is 195.95, while the estimate for category 853 including Electrical capacitors, Electrical resistors, Electric sound/visual signalling equipment etc. is 1.07.

⁷⁰Head and Mayer (2000) provide a nice summary and discussion of the alternative approaches of distance

the choice of alternative distance measures, we employ the procedure for distance calculation from Mayer and Zignago (2006).⁷¹ Their approach is appealing because it can be used to calculate consistently both internal distances and bilateral distances.⁷² In addition, we follow Eaton and Kortum (2002) to decompose distance effects into four intervals. The distance intervals, in kilometers, are: $[0, 3000)$; $[3000, 7000)$; $[7000, 10000)$; $[10000, \text{maximum}]$. Eaton and Kortum (2002) find that, with aggregate data, the estimate of the distance coefficient for shorter distances is larger (in absolute value) than for longer distances. This could reflect several forces. Motivated by transport costs, there could be mode choice switches (surface for short, air for long). But these switches could happen differently for different goods, which is particularly important for our disaggregated study, surface for heavy low value goods no matter how long the trip vs air for high value/weight goods even for quite short distances. Data on other standard gravity variables such as common language, common border, and colonial ties are from CEPII's *Distances* Database and from Rose (2004).⁷³ We also generate a border dummy variable 'same country,' which takes a value of one for internal trade.

calculations.

⁷¹Their procedure is based on Head and Mayer (2000), using the following formula to generate weighted distances: $d_{ij} = \sum_{k \in i} \frac{pop_k}{pop_i} \sum_{l \in j} \frac{pop_l}{pop_j} d_{kl}$, where pop_k is the population of agglomeration k in trading partner i , and pop_l is the population of agglomeration l in trading partner j , and d_{kl} is the distance between agglomeration k and agglomeration l , measured in kilometers, and calculated by the Great Circle Distance Formula. All data on latitude, longitude, and population is from the World Gazetteer web site.

⁷²In the few instances where we were not able to implement Mayer and Zignago's procedure, we just took the distance between the main cities from the two trading partners.

⁷³Rose's (2004) original data covers the period up to the year of 2000, so we update some of the variables in order to match the time span investigated in this study.
