The Great Escape: Intergenerational Mobility Since 1940

Nathaniel G. Hilger

NBER Working Paper No. 21217

May 2015

JEL No. J1,J24,J62,N01,N3,O15

ABSTRACT

Tax records indicate that intergenerational mobility (IM) has been stable for cohorts entering the labor market since the 1990s. I show that when using educational attainment as a proxy for adult income, stable IM is a new phenomenon: IM rose significantly for cohorts entering the labor market from 1940 to 1980. I measure IM directly in historical Census data for children still living with their parents at ages 22-25, and indirectly for other children using an imputation procedure that I validate in multiple data sets with parent-child links spanning the full 1940-2000 period. Post-war mobility gains were larger in the South and for blacks, and were driven by gains in high school rather than college enrollment. Controlling for region and year, states with higher IM have had lower income inequality, higher income levels, more educational inputs, higher minimum dropout ages, and lower teen birth rates. IM gains plausibly increased aggregate annual earnings growth by 0.125-0.25 percentage points over the 1940-1980 period.

1 Introduction

Intergenerational mobility (IM) is an important social objective for many individuals and policymakers, and may affect public attitudes toward other social objectives such as equality and growth (Piketty, 1995; Benabou and Ok, 2001; Corak, 2013). However, surprisingly little is known about IM variation over time, space and groups. The main empirical problem is that measuring IM requires data on labor market outcomes for both parents and children. No standard government data set has collected this information historically. A number of panel data sets contain this information, but they begin in the 1960s and are too small to examine mobility over time or subgroups with precision (e.g., Lee and Solon, 2009). While new administrative data sets are improving IM estimation in more recent periods, they do not shed light on long-term historical trends and they lack information on individual race and parental education (Chetty et al., 2014a). The lack of reliable, longer-term trends is unfortunate because the high school movement, early GI Bills, Great Society programs, several key Supreme Court decisions, and the Civil Rights movement all predate availability of most panel data sets.

In this paper I develop a new method to estimate IM statistics on U.S. census data. Prior research on IM has largely ignored census data. This is because the census only links parent and child outcomes while children still live with parents, and children rapidly become independent after age 17 but before any adult outcomes can be observed meaningfully (Cameron and Heckman, 1993). I develop a simple, semi-parametric adjustment for these “missing” independent children that allows me to estimate the conditional expectation function (CEF) of children’s final schooling as of ages 22-25 with respect to parental income or education.¹ Figure 1 illustrates these CEFs or “schooling gradients.” Adopting the terminology of Chetty et al. (2014a), I define the intercepts and slopes of schooling gradients as measures of “absolute upward” and “relative” intergenerational educational mobility, respectively.² Below I show in a stylized economic model that these relative IM statistics are closely related to each other and to more traditional IM statistics based on children’s earnings rather than children’s schooling.

The adjustment for independent children rests on two simple and verifiable assump-

¹I use the terms “schooling” and “education” interchangeably in the text to mean “highest grade attained.” I discuss problems with this variable in the Data section.

²The terminology of “upward absolute mobility” is more forced in my application because I am mostly working with child outcome levels rather than outcome ranks, but nonetheless has some intuitive appeal. I explore education ranks in Section 5.

tions. To illustrate, consider a toy example with two parental groups in a fixed year. Let children have either “high-income” or “low-income” parents. Among 22-year-olds, I observe 100 children living with high-income parents, 100 with low-income parents and 300 living independently, with average highest grade attained of 14, 12 and 12, respectively. I therefore observe a schooling gradient intercept of 12 years of schooling and a slope of 2 years of schooling across parental groups, but only for *dependent* children. I need to know two things to account for the remaining 60% of children who are independent: their parental group composition, and their average schooling by group. I first make a “parallel trends” assumption that the schooling gradient among independent children has the same slope as the gradient among dependent children: here 2 years. Now observe that virtually 100% of children up through age 17 still live with their parents. Suppose I observe 200 high-income and 300 low-income 17-year-olds. Under a second “smooth cohorts” assumption that parental group shares do not change across cohorts, I infer that 100 of the independent 22-year-old children have high-income parents and 200 have low-income parents. Let h equal average schooling of low-income 22-year-old independent children. We can now solve for h : $12 = \frac{100}{300}(h + 2) + \frac{200}{300}h \implies h = 11.67$. Total schooling of low-income children is therefore $\frac{100}{300} \cdot 12 + \frac{200}{300} \cdot 11.67 = 11.78$ and total schooling of high-income children is $\frac{100}{200} \cdot 14 + \frac{100}{200} \cdot 13.67 = 13.835$. The *total* schooling gradient therefore has intercept of 11.78 and slope of 2.055.

Below I formalize and slightly weaken these two assumptions of parallel trends and smooth cohorts, generalize the method to more than two groups, and present strong empirical evidence that both assumptions and the resulting gradients are valid in the U.S. historical context.³ I focus on ages 22-25. At these ages almost all children have completed schooling, but only about one third still live with their parents. The “parallel trends” assumption requires that children’s final schooling depends on parental group status in some way that is known up to a constant for dependent and independent children. This assumption would be violated if, for example, low-income children do not attend college, while high-income children who attend college move back in with their parents in early adulthood and high-income children who forego college live independently. I verify the parallel trends assumption directly in multiple data sets that contain parental group status for all children—not just dependents—including a matched panel linking 1930 and 1940 100% census microdata, the Panel Study of Income Dynamics (PSID), the National Longitudinal Study of Youth 1979 (NLSY), the Occupational Change in a Generation Surveys of 1962 and 1973 (OCG62, OCG73), and the General Social Survey (GSS). These

³In ongoing joint work with Ofer Malamud and Christian Pop-Eleches, we find that the key parallel trends assumption also holds up internationally across a wide range of countries.

data sets together span the entire sample period of 1940-2000. Remarkably, I fail to reject the parallel trends assumption in every data set and every subgroup I examine.

I can also directly validate the smooth cohorts assumption, which is milder and less surprising than the parallel trends assumption. Smooth cohorts would be violated if, for example, the share of children born to high-income parents vs. low-income parents in the U.S. changed in large, sharp ways over time.⁴ I verify the smooth cohorts assumption in census data using cohort trends for children during ages of near-100% dependent status. As the toy example above illustrates, the parallel trends and smooth cohorts assumptions together allow me to allocate the “de-linked” pool of age 22-25 independent children across parental groups, impute their final schooling, and average them with dependent children—thereby recovering the total CEF of final schooling with respect to parental group status. Finally, I show that the resulting gradients calculated by child’s state of birth are highly correlated with state-level income mobility statistics from administrative tax data for the 2000s.

The method opens up a wide range of new possibilities for research on IM because large, cross-sectional data sets such as the U.S. census are more widely available over time and space than panel data sets. As a first application of the method, I examine long-term IM trends in the U.S. I find that IM increased dramatically 1940-60, may have increased modestly 1960-1980, and stabilized thereafter. The level and stability of IM after 1980 line up with recent findings in the PSID (Lee and Solon, 2009) and tax records (Chetty et al., 2014b). However, the major increase after 1940 indicates that recent levels of IM are not a “deep” fact about the US economy, and that IM increased at the same time inequality declined (Goldin and Margo, 1992). I also replicate recent findings of lower IM in the South, but place this finding in its proper historical context of long-term regional convergence over many decades. IM gains were also slightly larger for men and much larger for blacks.

Post-war gains in IM were economically large. Back-of-the-envelope calculations suggest that the educational gains of poor children implied by the increase in relative IM may have raised aggregate annual earnings growth over the 1940-1980 period by 0.125-0.25 percentage points.⁵

I also shed some light on causes of these mobility gains. I show that increases in relative IM were driven by high school attendance rather than college attendance. Along with the facts above that gains were similar by gender and concentrated in years before 1960,

⁴I focus on native-born children to eliminate concerns about changes in selective immigration.

⁵These gains are reminiscent of the gains in allocative efficiency from reductions in occupational barriers facing women and minorities after 1960 (Hsieh et al., 2013).

the results argue against simple explanations based on the GI Bill, the War on Poverty or the Civil Rights Acts. Conditional on region and year, I find that IM by state-of-birth has positively correlated with higher income levels, lower income inequality, greater educational inputs, higher minimum dropout ages, and lower teen birth rates.

Prior literature has found mixed results on post-war trends in IM in the U.S. Hertz (2007) and Lee and Solon (2009) document stable mobility in child earnings since the 1970s, while Chetty et al. (2014b) confirm stable mobility in child income since 2000.⁶ I replicate these findings for recent decades, but place them in broader historical context. Aaronson and Mazumder (2008) develop a different method to estimate IM statistics on census data back to 1950 by instrumenting for parental income with cohort and state of birth. They find mixed results on IM trends before 1980 and declining IM after 1980. Olivetti and Paserman (2014) and Clark (2014) estimate trends in IM before 1940 using information about SES contained in children’s first and last names, respectively. As these authors carefully point out, their approaches depend on strong and unverifiable assumption that instruments (state of birth, last name, first name) only affect child outcomes through parental characteristics, or that biases induced by violations of this assumption are constant over time.⁷ The approach outlined here relies on weaker and more verifiable assumptions, at the cost of focusing on children’s final schooling rather than earnings or income. The method complements Olivetti and Paserman (2014) in that names data currently end in 1940, while income and education data begin in 1940. Finally, Long and Ferrie (2013) have compared long-term trends in intergenerational occupational persistence using both census and OCG data. As they point out (Long and Ferrie, 2013, footnote 14), occupational categories—unlike income and educational attainment—cannot be ranked cardinally over long periods of time. Moreover, reliance on OCG data precludes analysis of many subgroups due to sample size limitations.

The method developed here can enrich empirical analysis of dynastic human capital investment and the distribution of income (e.g., Becker and Tomes, 1979; Loury, 1981). Economists have typically disciplined these theories with a limited set of moments from small panel data sets in recent decades and high-income countries (Solon, 1999), and more recently with quasi-experimental estimates of causal effects on administrative data (Black and Devereux, 2011). If census data can generate IM statistics, relevant empirical moments become available across countries, regions, demographic groups, and time periods that can help to refine these models. I merely illustrate this possibility by examining

⁶Chetty et al. (2014b) estimate actual and predicted IM for children born 1970-1990, using child outcomes observed in years 1999-2012.

⁷This problem may be especially acute when focusing on subsets of unusual or prominent names (Chetty et al., 2014b, Appendix B). This is the case in Clark (2014), but not Olivetti and Paserman (2014).

and rejecting implications of a popular stylized model of dynastic human capital investment under liquidity constraints by Solon (2004) based on Becker and Tomes (1986).

The paper proceeds as follows. Section 2 outlines the problem of independent children that has prevented prior researchers from estimating IM on census data, develops a methodology for overcoming this problem, validates the two assumptions underlying this method, and compares the resulting IM statistics to analogous income mobility statistics from tax data by state of birth. Section 3 discusses the data sets I use in the analysis. Section 4 presents a simple model of parental income, children’s schooling, and borrowing constraints, and uses this model to show how measures of IM based on children’s schooling relate to each other and to more traditional measures of IM based on children’s income. Section 5 presents the main results. Section 6 explores potential explanations of new findings. Section 7 presents evidence from the OCG that higher educational mobility likely implies higher income mobility, consistent with the earlier comparison to income mobility estimates from tax data. Section 8 conducts several robustness checks on the main results. Section 9 briefly explores implications of the stylized model in more detail. Section 10 concludes.

2 A Solution to the Problem of Independent Children

2.1 The Problem of Independent Children

One useful class of IM statistics I refer to as “intergenerational *educational* mobility” (IEM) statistics relies on estimation of the CEF of children’s final schooling with respect to parental characteristics. Below I show that IEM statistics relate closely to IM statistics in a simple economic model, and I will often refer to them directly as IM statistics. The main reason research on IM has largely ignored the wealth of cross-sectional data sets is that such data only contain parental characteristics for the subset of children who still live with their parents. This is problematic because many children leave the parental home before they finish schooling, and the decision to move out may relate to schooling decisions in complex ways. This problem of independent children makes it hard to interpret IEM statistics calculated directly in most cross-sectional data sets (Cameron and Heckman, 1993).

Figure 2 displays this problem in census data in 1980 by plotting the fraction of children still living with their parents by age, alongside average schooling by age. The figure shows that children virtually all live with their parents up through age 16, but then begin to move out rapidly. Moreover, average schooling rises differentially across races long after many children have left the parental household. By the ages at which average

schooling stabilizes, nearly two-thirds of children have left the parental home, leaving researchers with a highly selected subsample of dependent children on which to calculate IEM statistics directly in census data.

2.2 A Solution to the Problem of Independent Children

I correct for the problem of independent children as follows. Let $h_{a,y}$ represent average years of completed schooling for children of fixed age a with parental income or education group y , with $h_{a,y}^D$ and $h_{a,y}^I$ indicating average years of schooling for dependent children still living with parents at age a and independent children, respectively. Similarly, let $N_{a,y}^D$ and $N_{a,y}^I$ indicate the number of dependent and independent children at age a . By definition,

$$h_{a,y} = d_{a,y}h_{a,y}^D + (1 - d_{a,y})h_{a,y}^I. \quad (1)$$

where $d_{a,y} = \frac{N_{a,y}^D}{N_{a,y}^D + N_{a,y}^I}$, or the “dependency rate” for children at age a in parental group y . Only a subset of these terms can be estimated directly in census data. For dependent children, I observe both average schooling and number of children for each parental group, h_y^D and N_y^D . For independent children, I only observe the total number of children N_a^I and overall average schooling h_a^I , pooling all parental groups. Because the census does not keep track of intergenerational links after children become independent, we do not observe schooling or frequencies for independent children by parental group, $h_{a,y}^I$ and $N_{a,y}^I$. I therefore need to estimate these unobserved terms in order to impute overall schooling by parental groups, $h_{a,y}$.

To proceed, I make and validate two simple assumptions: (1) a ***parallel trends*** assumption for dependent and independent children by parental group status, and (2) ***smooth group cohort size trends*** for parental groups. These assumptions generate a system of $2K + 1$ equations in $2K + 1$ unknowns that can be solved to identify average final schooling of children by age and parental group.

The ***parallel trends*** assumption states that:

$$f(h_y^D, h_y^I) = \rho \quad (2)$$

where $f(\cdot)$ can be any known function. I refer to this as “parallel trends” assumption because in practice I assume the function $f(h_y^D, h_y^I) = h_y^D - h_y^I$. This function places no restriction on the shape of children’s schooling gradients in parental income or education; it simply requires this shape to be equal up to a constant across dependent and independent children, where this constant is free to vary as determined by the data across time,

space, race, etc. One simple way in which this assumption could be valid is if dependent status after age 22 is exogenous to children's final schooling decisions conditional on parental group status. In fact, this stronger assumption turns out to be a reasonable approximation for whites in most years. However, the weaker assumption allows for a limited type of endogeneity and fits the data better more generally. The economic underpinnings of this assumption depend on complex, unobserved relationships between schooling, dependency, and parental group status. However, the assumption captures a simple and plausible intuition that parental income and education may correlate with children's schooling in ways that are not strongly related to residency choices in young adulthood, especially at ages after 22 when relatively few children are still attending college. Below I provide strong empirical support for this assumption.

The second assumption is *smooth cohorts*. Denote the total number of children in each parental group in cross-sectional data as $N_{a,y}$, where $N_{a,y} = N_{a,y}^D + N_{a,y}^I$. The assumption is that

$$N_{a,y} \approx g(N_{a-k-1,y}, N_{a-k-2,y}, \dots, N_{1,y}) \quad (3)$$

for a function $g(\cdot)$ that is smooth enough to be approximated by some parametric functional form, and where k captures the distance between the target age and the ages used in estimation. As shown for 1980 in Figure 2 and is true for other years, children do not leave home until after age 17. This implies that $N_y^I \approx 0$ before age 17. Under smooth cohorts, we can therefore estimate group cohort sizes at ages k years after 17 when schooling has been largely completed by estimating the function $g(\cdot)$ on group cohorts younger than 17. I then estimate parental group cohort sizes for independent children as $\hat{N}_{a,y}^I = \hat{N}_{a,y} - N_{a,y}^D$.

Under the assumption of parallel trends with $h_{a,y}^D - h_{a,y}^I = \rho$ and smooth cohorts, and for ages a at which children have completed schooling, I can estimate ρ as

$$\hat{\rho} = \left(\sum_{j=1}^K \frac{\hat{N}_{a,j}^I}{N_a^I} h_{a,j}^D \right) - h^I \quad (4)$$

I can therefore estimate average schooling for independent children in parental group y as $\hat{h}_{a,y}^I = h_{a,y}^D - \rho$. I then estimate final schooling gradients using equation (1).

A final problem with the estimator for ρ in equation (4) is that $\sum_{j=1}^K \frac{\hat{N}_{a,j}^I}{N_a^I}$ will not generally equal one due to measurement error in the $\hat{N}_{a,j}^I$ terms. The primary concern here is population growth, which would alter all parental group sizes (approximately) proportionally. I address this problem by substituting estimated total independents at

age a ($\hat{N}_a^I \equiv \sum_{j=1}^K \hat{N}_{a,j}^I$) for observed total independents at age a (N_a^I) in equation (4). This assures that $\sum_{j=1}^K \frac{\hat{N}_{a,j}^I}{\hat{N}_a^I} = 1$ and implies that $\hat{\rho}$ will be unbiased even if population growth changes parental group sizes across cohorts proportionally.

2.3 Validation of the Parallel Trends Assumption

Figure 3 presents non-parametric visual evidence on the validity of the parallel trends assumption in two leading panel data sets, the PSID and the NLSY79, both both parental income and parental education. The assumption appears approximately true. In addition to being parallel, the curves are not far apart from each other. This implies that errors in allocation of independent children to parental income groups due to violations of the smooth cohorts assumption are unlikely to significantly alter the final schooling gradients.

Figure 3 suggests that schooling gradients are approximately linear in parental income deciles, and in parental schooling above 10th grade. I therefore test the parallel trends assumption more formally using regressions of the following form:

$$h_{i,y}^j = \beta_0 + \beta_1 \cdot y + \beta_2 \cdot 1\{j = D\} + \beta_3 \cdot y \cdot 1\{j = D\} + e_{i,y}^j \quad (5)$$

where β_1 captures a linear trend in children's schooling by parental group status, β_2 captures a level shift in schooling across dependent and independent children, β_3 captures differences in the trend in parental group status across dependent and independent children. The parallel trends assumption can now be stated as the null hypothesis that $\beta_3 = 0$.

Table 1 presents estimates from this regression in parental income deciles. Columns (1)-(9) are based on the PSID. Column (1) finds no evidence to reject the assumption, pooling all years. Note that the overall gradient is large and highly significant, while the interaction term is small and insignificant. Columns (2)-(5) find no evidence to reject the assumption in any decade from 1970-2010. Columns (6)-(9) indicate the assumption holds for boys and girls, and for whites and non-whites. Column (10) finds no evidence to reject the assumption on the NLSY79, once again pooling all available years. I am unaware of any other data set in the U.S. with reliable information on parental income during adolescence and children's dependency status in young adulthood.⁸

Table 2 presents analogous evidence for schooling trends in parental education rather

⁸The Wisconsin Longitudinal Study does not track children's dependent status (personal correspondence with survey administrators). The GSS contains qualitative, retrospective parental income categories reported by children, and the OCG surveys contain quantitative, retrospective parental income categories reported by children. Parallel trends also hold in these data sets, but I omit them because they have no quantitative interpretation. Results available from author upon request.

than income. Note that for these estimates to correspond to Figure 3, it is necessary to reweight the data to give equal weight to each parental education category. I take a simple approach and simply collapse the data (using sample weights) to the level of dependent status by parental education group prior to estimating equation (5). I also restrict to parental education of at least 10 years in order to focus on the linear region of the curve in keeping with this specification. Columns (1)-(10) correspond to the analogous columns in Table 1. Columns (11)-(13) present additional evidence from the GSS, OCG62, and OCG73, all of which line up with results from the PSID and NLSY. The parallel trends assumption for both parental income and education therefore appears valid over the 1970-2010 period, with no evidence that this validity has varied substantially over time or demographic groups.

In order to assess parallel trends before the 1960s, I create a matched panel by linking children ages 10-17 in the 1930 census with children ages 20-27 in the 1940 census. This allows me to plot children's schooling outcomes by parental home value and rent groups; parental income and education are not available in 1930. I also restrict to boys due to changes in last names of girls after marriage.⁹

Figure 4 plots children's final schooling at ages 22-25 by parental home value and rent deciles, and for both whites and blacks. For whites, dependent and independent children at ages 22-25 have virtually identical schooling gradients. For blacks, the parallel trends assumption also holds, though the data are noisy in higher deciles. For blacks, though not for whites, allowing for a level shift fits the data significantly better.¹⁰ These results line up well with the results for later decades. Therefore, there is no evidence to reject the parallel trends assumption at any point in time since WWII, or for any subgroup for which sufficient data are available to implement a test.

2.3.1 Intuition for Parallel Trends

Some of the findings above support an even stronger assumption than parallel trends: overlapping trends. This would arise, for example, if determinants of dependent status at

⁹This exercise takes advantage of new digitized 100% samples of both 1930 and 1940 censuses. Following a stricter version of IPUMS practice, I link children based on five variables: birth cohort, state of birth, sex, race, first name and last name. I require exact, unique matches. Out of 7,284,262 children in the 1940 census, I match 1,483,889 or 20%, and about 70% of these matches are unique for a final match rate of about 14%. The resulting panel contains over 4 million children aged 20-27 with outcomes observed in 1940 matched to their age 10-17 parental characteristics in 1930.

¹⁰One might wonder why schooling declines so dramatically for blacks with the highest parental rent expenditures. There are very few blacks in these cells, and many of them may have reported rent incorrectly, for example reporting annual rent in place of monthly rent. This type of measurement error would generate the observed pattern, and is also consistent with the lack of a similar decline for blacks with the highest home values.

ages 22-25 were exogenous to final schooling conditional on parental group status. It is therefore interesting to note that the primary determinant of dependent status is marital status. Appendix Table A.1 displays the share of children age 22-25 who are married by decade and income decile in the PSID. Virtually no dependent children are married in any year, while 40-70% of independent children in every group are married. This suggests that children tend to leave the parental home when they find a spouse. It seems plausible that the exact age at which children find their spouses may not correlate strongly with factors mediating transmission of parental economic status to final schooling.

Other findings above only support parallel (not overlapping) trends. What is the intuition for this restricted form of endogeneity? A simple two-type example provides some insight. Let g represent a continuous measure of parental group status such as income or education. Suppose there are two types of children: high types H disposed toward higher levels of schooling $h_H(g)$, and low types L disposed toward lower levels of schooling $h_L(g) < h_H(g) \forall g$. Assume both types exhibit higher schooling in higher-status parental households such that $h'_H, h'_L > 0$. Let $p_D(g) \in [0, 1]$ indicate the prevalence of high types among dependent children, and likewise let $p_I(g)$ indicate the prevalence of high types among independent children. Suppose that high types are more prevalent among dependent children, i.e. $p_D > p_I$.

We can now write average schooling among dependent and independent children as

$$\begin{aligned} h_D &= p_D(g) h_H(g) + (1 - p_D(g)) h_L(g) \\ h_I &= p_I(g) h_H(g) + (1 - p_I(g)) h_L(g). \end{aligned}$$

We can then express the parallel trends assumption as

$$\frac{d(h_D - h_I)}{dg} = 0, \tag{6}$$

which can be shown to imply that

$$h'_H - h'_L = -\frac{(h_H - h_L)^2}{\rho} (p'_D - p'_I) \tag{7}$$

where $\rho = h_D(g) - h_I(g)$ equals the constant gap between parallel schooling gradients. Suppose $\rho > 0$ as we observe for blacks in 1940 with respect to parental home value and rent groups. Suppose that prevalence of high types increases more rapidly in parental status g for dependents than independents, i.e. $p'_D - p'_I > 0$. Now schooling of high types must increase *less* rapidly than low types. In other words, parallel but non-overlapping trends require that *behavior converges as composition diverges*. The required convergence

of behavior across types per unit of differential change in prevalence is decreasing in the gap between dependent and independent schooling ρ , and increasing in the level of behavioral differences across types.

At least qualitatively, this is a natural assumption to make in the context of schooling gradients and parental group status. For example, ability and many other determinants of schooling may change differentially among dependents and independents as parental status increases. But ability likely has smaller impacts on final schooling outcomes in higher-status families. This type of force may serve to stabilize dependent-independent child outcome differences across parental groups, even if selection on child type into dependent status also varies across parental groups.

2.4 Validation of the Smooth Cohorts Assumption

I exploit the smooth assumption to predict total parental group cohort sizes—including both dependent and independent children—at ages 22-25 using cohort sizes prior to age 17, when virtually all children live with parents and can therefore be linked to parental groups. This prediction requires selection of an estimator.¹¹

I employ a simple method to select and validate an estimator. The approach I take is to evaluate potential estimators of total group cohort sizes ten years earlier at ages 12-15 using group cohort sizes up through age 7. If the best estimators perform well at these ages when true group cohort sizes are observed, then these estimators will likely perform well when using group cohort sizes up through age 17 to predict group cohort sizes at ages 22-25, when true group cohort sizes are not observed. The assumption here is that parents do not change income and education groups in sharp ways over the ten years that elapse between the “validation” ages 12-15 and the “prediction” ages 22-25.

The approach is easy to understand visually. Figure 5 plots the number of children

¹¹It might seem that I could observe parental group cohort sizes almost perfectly in the prior census. This is not true for several reasons. First, both income and education are not observed in 1930, preventing the use of this method to estimate parental group cohort sizes in 1940. Since gradients cannot be estimated in the 1950 census, it is critical that I develop a method that can be applied to the 1940 census if I am to significantly extend the historical record for IM. Second, parental group status may change in systematic ways over ten-year intervals. For example, parents of 12-15 year-olds in the bottom income decile in 1960 may not systematically be in the bottom income decile as parents of 22-25 year-olds in 1970. This consideration is less important for parental education, but still may exist due to variation in survey methodology and due to recall bias known as “education creep” (Denison, 1962), and it is useful to construct all gradients in a similar way for comparability. A less serious problem is that ten years of death and migration take place between censuses. This problem would be small in my application because few 12-15 year-old children die before turning 22-25 during this period, and because I restrict samples to native-born children. The problem of immigration would be more serious for other demographic groups such as Hispanics and Asian Americans, especially if some families misrepresent their children’s place of birth to census enumerators.

living with parents in different income deciles by age in 1940. The figure suggests that we could predict cohort size at ages 12-15 quite well using cohort sizes at ages prior to 8. This suggests that in 1950, we can predict cohort sizes at ages 22-25 using cohort sizes at ages prior to 18. While no income data is available in the 1930 census to perform this exercise, the figure also suggests that cohort sizes before age 17 appear likely to perform well as predictors of cohort sizes at ages 22-25.

Tables 3 and 4 present results of this exercise more formally for parental income and education groups, respectively. Each column displays results from a regression of group cohort size share at ages 12-15 on some estimator based on group cohort size shares before age 8.¹² Columns 1-3 experiment with different estimators, pooling all years 1940-2000. The simplest estimator based on cohort size at age 7 performs reasonably well relative to more complex estimators. I rely on this simple estimator for all main results for this reason and because it is more stable for smaller subgroups. Columns 6-12 examine this estimator by year.¹³ Several lessons are apparent from these tables.

First, the estimators are highly statistically significant in every year, indicating substantial power to identify the parental group composition of independent children. Second, the coefficients on the estimators are typically close to one, with no particularly alarming pattern over time. The predictions for the parental education groups are somewhat more accurate than for parental income groups, though both are excellent. Appendix Tables A.2 and A.3 display similar patterns for black children.

The results in this section support the smooth cohorts assumption. Group cohort sizes evolve in predictable ways and thereby permit credible estimates of parental group composition among independents.

2.5 Direct Validation with Tax Data

Results above validate the two key assumptions underlying the proposed methodology. It is also possible to validate the resulting mobility estimates themselves against an alternative, high-quality source. Such data have recently been made available for the 2000s by Chetty et al. (2014a), who estimate slopes and intercepts from regressions of child income ranks on parental income ranks in every “commuter zone” (CZ) in the U.S. using the population of U.S. tax records. For comparison, I average these income-based rank-rank slopes up to the state level.¹⁴ I then construct schooling rank-rank slopes on

¹²Recall that gradient estimation only depends on group cohort shares, not group cohort levels.

¹³Similar patterns by year hold for all of the estimators.

¹⁴The resulting state-level intercepts and slopes should come close to what would be obtained from a rank-rank regression on state-wide micro-data. Such a regression would average the CZ-level slopes with weights proportional to the variance of parental income rank in each CZ (Angrist and

census data by state, using the adjustment for independent children. Note that state-level schooling mobility estimates in census data are quite noisy because IPUMS only provides a 5% sample in 2000, the education distribution is much lumpier than the income distribution, and the state size distribution is skewed. To increase precision, I therefore pool censuses from 1980, 1990 and 2000, and focus on the 25 largest states over this period.¹⁵ A final consideration is that Chetty et al. (2014a) typically measure children’s residential location around age 15. I can either measure children’s location at ages 22-25, or at time of birth. I choose time of birth because many college graduates will have left their home states as of ages 22-25.

Figure 6 plots mobility estimates from census data against mobility estimates from tax data. The correlation between the intercepts in Panel (a) is 0.81, while the correlation between the slopes in Panel (b) is 0.71. These results provide strong direct evidence that the method developed here for constructing mobility statistics generates meaningful results. This conclusion is not surprising given the validation results above for the two key underlying assumptions of the method.

3 Data

The decennial census is the only large-scale, nationally representative source of data on income and education before the 1960s in the U.S.¹⁶ I rely on census data from 1940-2000, when income and education are both available. I also make full use of the recently-available 100% digitized sample of the 1940 census.¹⁷

I also incorporate data from the Panel Study of Income Dynamics (PSID), the National Longitudinal Survey of Youth 1979 (NLSY), the Occupational Change in a Generation 1962 and 1973 surveys (OCG62 and OCG73), and the General Social Survey (GSS) to assess some of the assumptions underlying the empirical strategy. These PSID and NLSY79 are panel data sets that track children after they split into new households, and for my purposes cover children back to 1968 and 1994, respectively. The OCG surveys are one-time cross-sectional data sets that collect information on adults and their parental characteristics during adolescence. The GSS is an annual cross-sectional survey that collects information on parental income and education, and begins in 1972 for the US.

Pischke, 2009). I use unweighted averages, although I experimented with weighting by CZ-level Gini coefficients and interquartile ranges as two proxies for parental income rank variance, and found these alternative weights had virtually no impact on the results.

¹⁵Pooling 1980-2000 is justified by results below confirming stable mobility over this period.

¹⁶The Annual Social and Economic Supplement of the Consumer Population Survey (the March CPS) begins in 1962 and excludes military and incarcerated individuals from its sample (Neal, 2006).

¹⁷All Census data sets obtained from Ruggles et al. (2010).

There is some ambiguity in dependent status of young adults in “group living” situations such as college dormitories, prisons, and military barracks in census data National Research Council (2006). Since 1850, instructions to enumerators (1850-1950) and to survey respondents (1960-2000) have indicated that children who are living away from home for college should be counted at their college residence and not as part of their family (e.g., Bureau of the Census, 1988; National Research Council, 2006, p. 47). Note that living away at colleges is not a major issue for my results because I focus on ages 22-25, and very few children live in college dormitories at these ages. However, prisons and military barracks may be important, especially for black men in more recent decades (Neal, 2006). For my primary results I count all of these children as independents; in the Robustness section I show results are similar if I omit them from the analysis.

Income and earnings are reported retrospectively in census data, and many families report zero and missing values. I choose to exclude zeros from the baseline analysis because zeros represent a combination of genuine zeros and measurement error, and the exact mix may vary across demographic groups and years. I examine the sensitivity of my results to this and other assumptions in the Robustness section.

Educational attainment is subject to another type of measurement error as documented by Margo (1986). Before 1920, many blacks, especially blacks in the South, attended ungraded schools. While educational attainment in the census is supposed to represent highest grade completed, enumerators were instructed to elicit number of years spent in school from individuals who attended ungraded schools. In practice, this means that many black parents in the 1940 and possibly 1960-70 censuses who report low levels of educational attainment probably have even lower levels of attainment due to slower annual progress in ungraded schools. If the true child outcome gradient were linear in parental highest grade completed, then this problem would shift some parents with very low attainment into the moderate attainment region and generate a more U-shaped estimated gradient in 1940 relative to later years. I do not find substantial evidence for this, and I therefore do not focus on this problem. Moreover, the problem does not affect schooling of children in my sample, and therefore has no impact on gradients measured in parental income, which exhibit similar qualitative patterns as gradients measured in parental education.

4 Economic Interpretation of Gradients

How should we interpret measures of mobility based on children’s schooling rather than children’s earnings? And how do mobility measures based on parental income and

parental schooling relate to each other? In this section I present a simple model of borrowing constraints and schooling developed in Solon (2004) to address these questions, modified to allow for parent-child income transmission through both human capital and other factors. The model is highly stylized and only intended to provide basic intuition for relationships between different measures of intergenerational mobility.

Let a parent with one child maximize a Cobb-Douglas utility function

$$U_i = (1 - \alpha) \ln C_{i,t-1} + \alpha \ln y_{i,t} \quad (8)$$

where i indexes individuals, t indexes a generation, $C_{i,t-1}$ denotes parent's own consumption, $y_{i,t}$ denotes the child's future pre-tax income, and α governs the trade-off between own consumption and children's income. The parent maximizes utility subject to a budget constraint

$$(1 - \tau) \cdot y_{i,t-1} = C_{i,t-1} + I_{i,t-1} \quad (9)$$

where τ is the average and marginal tax rate on parental income, $y_{i,t-1}$ denotes parental pre-tax income, and $I_{i,t-1}$ denotes financial investments in children's human capital. These financial investments yield decreasing marginal returns subject to the human capital production function

$$h_{i,t} = \delta + \theta \ln (I_{i,t-1} + G_{i,t-1}) + e_{i,t} \quad (10)$$

where δ represents the minimum schooling level in society, θ represents the productivity of financial investments in human capital, $G_{i,t-1}$ represents government spending on human capital of child i , and $e_{i,t}$ captures human capital transmitted to children from parents through channels other than financial investment. Assume that government education spending is allocated progressively such that

$$\frac{G_{i,t-1}}{y_{i,t-1}} \approx \varphi - \gamma \ln (y_{i,t-1}), \quad (11)$$

where φ indicates the universal subsidy as a share of income, and γ captures progressivity of the subsidy schedule.

Assume a log-linear earnings equation in schooling in the tradition of Mincer:

$$\ln y_{i,t} = \mu + p h_{i,t} + \varepsilon_{i,t} \quad (12)$$

where p indicates the return to schooling, μ is the minimal income level in society, and

$\varepsilon_{i,t}$ captures income transmitted to children from parents through channels other than observed human capital.¹⁸

Let heritability of both $e_{i,t}$ and $\varepsilon_{i,t}$ be governed by the same AR(1) process such that

$$e_{i,t} = \lambda e_{i,t-1} + \nu_{i,t} \quad (13)$$

$$\varepsilon_{i,t} = \lambda \varepsilon_{i,t-1} + u_{i,t} \quad (14)$$

where λ indicates the degree of human capital and income inherited from parents outside of monetary investment channels. The assumption that one parameter governs both these inheritance processes is made for analytical convenience.

Letting $\beta_{x,x'}$ denote the OLS coefficient from a regression of x on x' , it can be shown that in steady state

$$\begin{aligned} \beta_{h_t, h_{t-1}} &= \frac{p\theta(1-\gamma) + \lambda}{1 + p\theta(1-\gamma)\lambda} \\ &= \beta_{\ln y_t, \ln y_{t-1}}. \end{aligned}$$

This result suggests that intergenerational relative mobility in terms of education should be similar in magnitude to intergenerational relative mobility in terms of income. This key finding is consistent with evidence I present below comparing my estimates of $\beta_{h_t, h_{t-1}}$ with estimates of $\beta_{\ln y_t, \ln y_{t-1}}$ from other sources.

Again assuming steady state, it can be shown that gradients in parental education and parental income are related by:

$$\beta_{h_t, \ln y_{t-1}} = -\left(\frac{1}{p}\lambda\sigma_\varepsilon^2\right) + \frac{1}{p} \cdot \beta_{h_t, h_{t-1}}. \quad (15)$$

This result clarifies why the relationship between the two types of gradient might vary over time and groups. For example, if the conditional variance of income rises, then $\beta_{h_t, y_{t-1}}$ will fall relative to $\beta_{h_t, h_{t-1}}$. Second, the result suggests that the relationship between the two gradients contains information about other parameters in the model. This relationship is more complicated than it appears because some of these parameters also enter into $\beta_{h_t, \ln y_{t-1}}$ and $\beta_{h_t, h_{t-1}}$. Below I explore the plausibility of the estimates implied

¹⁸Note parents cannot increase child income directly with bequests in this model; human capital is the only instrument for transfers. To add savings, let $\ln(y_{i,t} - S_{i,t}) = \mu + ph$ and augment the budget constraint to $y_{i,t} = C_{i,t} + I_{i,t} + S_{i,t}$. In this extended model, for incomes above a critical value savings are positive and parental income has no causal impact on children's schooling but still has a positive regression coefficient due to the non-financial transmission parameter λ , as expected.

by this relationship under some additional assumptions. Finally, the model also suggests a number of comparative statics for the education gradients: $\beta_{h_t, h_{t-1}} (\theta \uparrow, \gamma \downarrow, \lambda \uparrow, p \uparrow)$, $\beta_{h_t, \ln y_{t-1}} (\theta \uparrow, \gamma \downarrow, \lambda \leftrightarrow, p \leftrightarrow, \sigma_\varepsilon^2 \downarrow)$. In theory, these comparative statics can shed light on potential causes of mobility variation over time and groups.

5 Results

Figure (7) presents the two estimated gradients in 1940 before and after the correction for independent children. The correction turns out to affect levels much more than slopes because dependence rates turn out to be roughly stable across parental groups at ages 22-25 in census data. The correction also affects blacks more than whites due to the larger share of young adult blacks living independently. Note that adjusted gradients remain precise for blacks despite having only one tenth the population of whites.¹⁹

Figure (7) previews two other patterns of interest. First, relative mobility is strongly correlated with absolute upward mobility because the gradients “pivot” at high levels of parental income and education. In other words, poor children vary much more across groups than rich children. Second, the gradients are approximately linear in parental income rank. These patterns echo recent findings on intergenerational mobility in administrative data in ?, but 60 years earlier in time.

I now examine final schooling gradients non-parametrically by year. Figure 8 plots corrected schooling gradients in parental education for whites.²⁰ The gradients display a clear increase in both absolute and relative mobility over time. Figure 9 plots analogous gradients in three functions of parental income: deciles, levels and logs. The figure displays a striking increase in schooling levels among the poorest children from 1940-1980, with little change thereafter. Schooling is concave in the level of parental income, slightly convex or S-shaped in log of parental income, and linear up through the 90th percentile in rank of parental income. These curvature patterns are similar to patterns for children’s income gradients in the 2000s found by ? in administrative data, and are roughly consistent with the model except for the rejection of gradient linearity in the log of parental income. The rank specification is well-suited to furnish reliable measures of mobility because it does not depend on changes in the parental income distribution and because it happens to be approximately linear.

¹⁹In ongoing work, I show the correction also yields precise estimates for Asian-Americans, the original “model minority” Petersen (1953), and a group that is only 1% as large as whites and therefore, to my knowledge, impossible to study intergenerationally outside the census.

²⁰Gradients cannot be constructed for the 1950 census because only one individual per family received the census long form with questions about income and education, making it impossible to relate parental income to child outcomes.

Having established that gradients are approximately linear in parental education levels and income deciles, I now report estimated intercepts and slopes of schooling gradients. Tables 5-8 display estimates of intercepts and slopes for schooling gradients in parental education levels and income deciles, for whites and blacks separately, i.e., the estimates displayed in Figures 8 and 9.a. Each column represents estimates from a regression of the form

$$h_{y,t} = \sum_{t=1940,1960,\dots,2000} \alpha_t \cdot 1 \{\text{year} = t\} + \sum_{t=1940,1960,\dots,2000} \beta_t \cdot 1 \{\text{year} = t\} \cdot y, \quad (16)$$

where $h_{y,t}$ represents a child outcome measure, t indexes census year, and y indexes parental group (either education or income decile) normalized such that the lowest-SES group has $y = 0$. Note that the constant terms are omitted from these regressions. The coefficients α_t and β_t represent absolute upward mobility and relative mobility, respectively, in year t .

Column (1) from these four tables contains estimated intercepts and slopes for the two gradients, and for whites and blacks separately. I display these estimates graphically in Figures 10 and 11. These figures additionally compare the estimates with corresponding statistics from the PSID based on actual parent-child links. The census and PSID estimates line up reasonably well. The estimated slope of the gradient in parental education in 2000 for whites is 0.278 (SE=0.020), which is in the range of the estimated intergenerational income elasticity on tax data in years 2011-12 reported in Chetty et al. (2014a, Figure 1.B) of 0.344 (SE=0.000), as predicted by the model above.²¹ In addition, the estimate of the intergenerational elasticity for whites in 1940 of 0.398 (SE=.0218) in Table 5 is very close to the estimate obtained for whites in 1940 by Olivetti and Paserman (2014).

The figures replicate recent findings of stable IM since the 1980s (Lee and Solon, 2009; ?), but indicate this period of stability followed a dramatic increase in IM after WWII.²² The long-term trend emerges in both types of gradients, in both absolute and relative IM measures, and in virtually all demographic groups. However, the increase was larger for some groups than others. The gain was much larger for blacks than whites. Both

²¹The difference could arise due to a violation of the model equating the two statistics, or to measurement error in education data in the census, or to instability of the intergenerational elasticity due to underlying nonlinearities in the CEF. In contrast to the gradient in parental education, the gradient in parental *income* that I estimate here has a much higher intercept and lower slope than that reported in Chetty et al. (2014a) based on five-year averages of parental income, as would be expected from substantial measurement error in census income data.

²²Formal tests for equality of parameter estimates across years with very different point estimates generally yield p-values well below 5%.

absolute and relative mobility were much lower for blacks than whites in 1940, with approximate convergence achieved in both measures by 1980.

The absolute and relative gains of black children are especially remarkable. The lowest-income black children nearly *doubled* their final schooling from 6 to 12 years between 1940 and 2000, about twice the gain made by the lowest-income white children, which is large in its own right. These gains reduced the schooling gap between bottom and top income decile blacks by 75%, or 4.5 full years of schooling. These results here show that 20th century black-white economic convergence (see, for example, Smith, 1984; Margo, 1994) can be understood not only as blacks converging toward whites, but as poor blacks converging toward rich blacks, and rising mobility more generally.

Columns (2)-(3) of Tables 5-8 display results for boys and girls separately. The increase in absolute and relative IM affected boys somewhat more than girls. Columns (4)-(5) break out results into South and Non-South census regions. These results replicate findings that the South exhibits lower IM than other parts of the country in the most recent period (Chetty et al., 2014a). However, the longer time-frame allowed by census data reveals that this IM gap is very small in historical context, and follows in the wake of dramatic regional IM convergence from radically different initial conditions. Unsurprisingly, the mobility gains in the South were particularly large for blacks, though they were also substantial for whites. Figure 12 displays the estimated slopes of both gradients for whites only in the South and Non-South and vividly conveys the long-term convergence pattern.

These increases in IM since WWII have not previously been documented, and they are economically large. To see this, consider the impact of the increase in relative mobility with respect to parental income. Suppose relative educational mobility in 1980 remained at the 1940 level, so that schooling at the top decile in 1980 were held constant at its observed value but schooling of all lower deciles were decreased to reflect the steeper slope from 1940. This would reduce average schooling in 1980 by about one year. One year of schooling during this period increased earnings by around 5-10%. This would account for about 0.125-0.25 percentage points of economic growth over the 1940-1980 period. This transitory growth effect is conceptually related to that obtained from improving occupational opportunities for women and minorities, as in Hsieh et al. (2013).

The method here can also be used to estimate mobility statistics in terms of children's and parent's education *ranks*.²³ This approach has two main advantages. Ranks facil-

²³I confirm that the parallel trends assumption remains approximately true for education ranks in the PSID, with respect to both parental income and education ranks. Results available from the author upon request.

itate comparison of gradients over time as the underlying distributions of educational attainment evolve. Second, rank gradients allow a cleaner interpretation of intercepts as absolute upward *mobility* distinct from secular gains in education. However, these advantages come at a cost: rank gradient properties cannot be interpreted in terms of human capital units, and ranks can be unstable for distributions of random variables such as educational attainment with small numbers of large, changing mass points.

Table 9 displays gradient intercept and slope estimates analogous to those in Tables 5-8, but now in education ranks on a scale of 0 – 100 for both children and parents, with ranks calculated separately at each age for all children and parents. For blacks (Columns (2) and (4)), rank gradients exhibit patterns similar to level gradients: large improvements in both absolute upward and relative mobility over time, especially during the 1940-60 period. For whites (Columns (1) and (3)), rank gradients in parental income suggest minimal gains in absolute upward mobility, but significant gains in relative mobility. Rank gradients in parental education do not exhibit a clear trend over time and appear somewhat unstable, perhaps due to changes in the mass points and underlying educational attainment intervals for both children and parents.²⁴

6 Mechanisms: What Caused the Increase in Intergenerational Mobility?

What accounts for the increase in educational attainment of poor children after 1940? While a full answer to this question is a task for future research, I venture a brief discussion here.

High School vs. College Enrollment. The largest changes took place between 1940-1960, before the Great Society programs and the Civil Rights movement. Given that the poorest children had zero years of high school education on average in 1940, high schools rather than colleges most likely account for this increase in schooling among the poor. In order to explore the different contributions of high school and college I examine

²⁴For example, in 1940 many parents have mass in the attainment range of 5-8 years of schooling, which I lump together as “6.5” years of schooling, whereas in later years most mass occurs at 12 and 16 years of schooling. Changing lumpiness of attainment distributions over time might explain why these national rank-rank educational mobility statistics appear unstable over time, but are highly correlated with rank-rank income mobility statistics across states at a fixed point in time as shown in Section 2.5.

Note that when rank gradients in parental education are constructed on just the sample of dependent children, they exhibit the same increase in absolute upward and relative mobility over time as the education level gradients. Incorporating independent children as I do in the text flattens out the gradients in earlier years by altering the mapping from education levels to ranks.

school enrollment rates separately for high-school-going ages 16-18, and college-going ages 19-21.²⁵

Columns (6)-(7) of Tables 5-8 display the results. For whites, both absolute and relative mobility in high school enrollment increased substantially. For college enrollment, however, only absolute mobility increased, while relative mobility actually fell significantly. After sixty years of policy initiatives designed to increase college affordability including the GI Bills, the community college movement and large expansions of federal financial aid, poor children have made substantial gains in college access, but have made no gains at all *relative* to rich children. For blacks the story is similar, though estimates are less precise. These estimates place recent work on college access into longer-term historical perspective (e.g., Lochner and Monge-Naranjo, 2011; Bailey and Dynarski, 2011; Belley and Lochner, 2007). It is worth noting here that high school enrollment, unlike college enrollment, has been “free” to families throughout the 20th century.

Black-White Convergence. Why did mobility increase so sharply for blacks? The answer likely involves the well-documented gains in school quality and access throughout the early-to-mid 20th century due to both supply and demand factors (e.g., Smith, 1984; Card and Krueger, 1992; Margo, 1994; Donohue III et al., 2002; Aaronson and Mazumder, 2011). Many of these factors would be expected to increase schooling of lower-SES black children disproportionately. Geographic correlates with mobility presented below for both blacks and whites shed further light on this issue.

The Great Depression. Does low mobility in 1940 represent a different steady state, or does it represent a temporary aberration from historical trends in the wake of the Great Depression? I can explore this question by extending mobility estimates back to 1930, just after the Great Depression had begun. While income and education are not available in 1930, enrollment, home value and rent can be used to construct alternative gradients of child outcomes in parental economic status. I construct gradients of enrollment age 16-18, as above, by home value and rent deciles separately. Note that while renters are somewhat lower-income than owners, the rent and home value distributions comfortably span the income distribution in 1940. While composition of these groups changes dramatically 1940-60 due to the dramatic post-war increase in homeownership, both ownership rates and home prices were surprisingly stable 1930-40.²⁶

²⁵Note that for enrollment gradients in parental education, I exclude parental education levels below 9, whereas I exclude parental education levels below 6.5 in other columns. The reason for this is that enrollment gradients are nonlinear; they are largely flat or downward-sloping below parental grade 9, but linearly increasing after grade 9. The main qualitative lessons here hold for the full gradients but cannot be captured by linear regressions.

²⁶Home prices fell by much less during the Great Depression than they did during the Great Recession, and increased by about 10% over the full 1930-40 period (Shiller, 2015).

I display the results in Figures 13-14. Mobility in college enrollment appears nearly identical in 1930-40, and highly consistent with the patterns described above for college mobility in parental income and education. Mobility in high school enrollment was already low in 1930, but it did decline slightly by 1940 as substantial enrollment gains passed by the lowest-SES children.²⁷

Geographic Correlates. Results above on Southern mobility gains and a growing literature on spatial variation in mobility (Jantti et al., 2006; Corak, 2006; Chetty et al., 2014a) suggest an important role for institutional variation over space. To explore geographic variation I calculate mobility statistics separately by state of birth and year, again focusing on four types of statistics: intercepts and slopes of gradients in parental income ranks and education levels. Inspection revealed that the magnitude of the slopes increased steadily in the R-squared of the underlying gradients, suggesting an important role for specification or measurement error in these statistics. I therefore restrict to intercepts and slopes of linear gradients with R-squared of at least 0.5. Note the direction of these correlations is more robust than their exact magnitude and statistical significance, and results should be interpreted with caution.²⁸

Tables 10-11 present correlations of mobility statistics with various state-level, time-varying characteristics for whites and blacks, respectively. In order to abstract from regional and temporal variation already discussed, I first regress mobility statistics and all state characteristics on a complete set of region by year interaction dummies, using the four census regions. Following Chetty et al. (2014a), I then convert all residuals into z-scores to obtain correlations and standard errors by regressing these residual z-scores of mobility statistics on residual z-scores of state characteristics. Each column contains correlations of the named state characteristic with four different measures of mobility that correspond to absolute and relative mobility using parental education and income groups. Column (1) uses the average of log income in state by year cells as a measure of economic development. Column (2) uses the interquartile gap in log incomes within state by year cells as a measure of inequality. Columns (3)-(5) use minimum school dropout age, average class size, and relative teacher pay as measures of school quality. Columns (6) and (7) use the teen birth rate (age 14-19) and black population shares, respectively.

All significant coefficients go in the “expected” directions, to the extent expectations

²⁷A decline in mobility from 1930-40 would conflict with rising mobility 1920-1940 suggested by results in Olivetti and Paserman (2014). Unfortunately, pre-1940 census variables used in all of these gradients do not pin down child and parent economic status as persuasively as the education and income data that only become available in 1940.

²⁸I experimented with restricting the sample based on R-squared and state sample size, and using gradients in child and parent education ranks rather than levels. I leave more thorough investigation of these correlations for future research.

exist. Mobility tends to increase in state income levels, lower inequality, higher school dropout ages, smaller class sizes, higher teacher pay, and lower teen birth rates.²⁹ The most salient difference between correlations for blacks and whites is the large and significant negative correlation of black population share with mobility for blacks. Margo (1994) documents evidence that school quality for blacks suffered in states with larger black population shares due to stronger incentives of whites to shift resources from black to white schools. The correlations here suggest this pattern may have disproportionately affected lower-SES black children.

7 Did Higher Educational Mobility Lead to Higher Income Mobility?

A key finding of the paper is that intergenerational mobility in terms of children's schooling increased significantly after 1940. This raises the question of how these changes in educational mobility translate into income mobility. Validation of state-level estimates against income mobility in tax data indicates the answer is yes for recent cohorts (see Section 2.5). Here I also address this question for earlier cohorts in the OCG1962 and OCG1973 surveys, which contain parental education levels and larger samples than the PSID or NLSY79.³⁰ I first ask if education affects income of children from different parental groups in similar ways. If that were the case, it would suggest that IEM likely translates into IM, and that we can link these two concepts together with this shared return to schooling as assumed in the model of Section (4).

To proceed I decompose children's earnings into three factors: returns to education, returns to parental group status unrelated to education, and differential returns to education by parental group status, by estimating regressions of the form

$$\log \text{Earnings}_{g,\text{educ}} = \alpha + \beta \cdot \text{educ} + \gamma_g \cdot 1\{\text{fatherEduc} = g\} + \delta_g \cdot 1\{\text{fatherEduc} = g\} \cdot \text{educ} \quad (17)$$

for individuals in 10-year birth cohort groups separately on OCG73 and OCG62 data.

²⁹The equality of correlations in row (4), columns (1) and (2) of Table 10 is not exact and appears to be driven by chance.

³⁰An alternative approach is to use the 1930-40 matched census data, which contains parental home value and rent in 1930, and compare children's income mobility in that panel data to income mobility in more recent panel data such as the PSID, which also contains parental home value and rent. The main problem with this approach is that the housing market underwent a transformation from 1940-60 and the homeownership rate increased by 50%. It is therefore difficult to compare mobility among children of homeowners or renters in 1940 with mobility among children of homeowners or renters after 1960 due to this large shift in the composition of both owner and renter samples.

Here β captures a shared return to schooling, γ_g captures effect of parental background on earnings through non-education channels such as family connections, and δ_g captures differential returns to schooling by parental status due to factors such as quality of education or academic ability.

Table 12 Columns (1)-(5) present the results. I do not reject the hypothesis that returns to schooling (β) are the only determinant of children's earnings for any cohort in either OCG data set. I am unable to reject the hypothesis that other factors (γ_g and δ_g) changed in ways that could have offset the educational gains of children from low-SES parents. However, the point estimates decline across cohorts, which would amplify effects of increasing educational mobility on income mobility.

Therefore changes in children's education likely imply changes in children's earnings across all parental status groups. I now ask if higher income mobility can be observed directly in the OCG data. For this exercise, I estimate children's education and income gradients separately with respect to father's education, allowing the intercept and slope of this relationship to change across cohorts. Specifically, I estimate equations of the form

$$\text{childOutcome}_{g,c} = \pi + \phi \cdot \text{fatherEduc} + \eta_c \cdot 1 \{ \text{cohort} = c \} + \lambda_c \cdot 1 \{ \text{cohort} = c \} \cdot \text{fatherEduc} \quad (18)$$

for individuals in the same 10-year cohorts as before, where $\text{childOutcome}_{g,c}$ is either log earnings or education, father's education varies from 7 to 17 years of completed schooling, π and ϕ capture the intercept and slope of the outcome gradient, respectively, and the η_c and λ_c terms capture changes in the intercept and slope, respectively, across cohorts. I select cohorts that correspond roughly to cohorts of 22-25 year-olds in the 1940, 1950 and 1960 censuses. These cohorts have earnings that can be observed after age 27 in OCG data sets (except for the 1940 birth cohort in OCG62) and span the key educational mobility gains documented above.

Table 12 Columns (6)-(9) present the results. The education gradients are similar to those estimated above on census data, and display similar increases in intercepts and decreases in slopes as in census data, although much less precisely. First note that a return to schooling around 10% per year suggests that education by itself can explain about 75% ($= 0.1 \times 0.429 / 0.055$) of the gains from having higher-education parents. I have also replicated this pattern in the 1930-40 matched census panel for parental groups defined by home value and rent; there education by itself can explain about 50% of the gains from having higher-status parents.

Second, note that the gains in educational mobility with respect to parental education

that I document above suggest the gradient rotated up by about one year for children of the lowest-education parents. Returns to schooling of 10% per year therefore imply that the income gradient in parental education should increase by 0.1 log points in the intercept and, given the domain of father’s education from 7-17 years, should decrease the slope by about 0.01 log points. This is close to the results in Column (7) for the OCG1973, though again results are imprecise. In OCG1962, I cannot observe income for the cohort corresponding to the 1960 census with precision, and results are too imprecise to be useful for the cohort corresponding to 1950. Overall, these results do suggest that gains in educational mobility imply gains in income mobility, but are too noisy to demonstrate this conclusively. This is not surprising given that the motivation for this paper stems from a lack of any precise, long-term historical time series data on intergenerational income mobility.

8 Robustness Checks

I have focused on solving the problem of independent children. Another problem with census data are that they only contain information about parental income in a single year. This may be especially problematic when comparing gradients across races with very different permanent incomes (Rothstein and Wozny, 2014). In Appendix A.1 I develop a simple method to correct for permanent income differences across races in the PSID. I conclude that permanent income differences are not likely to be driving my estimated differences in relative mobility across racial groups. And of course the mobility gradients that rely on parental education are not affected by permanent income differences across races.

As discussed above in the “Data” section, there is some ambiguity in dependent status of young adults in “group living” situations such as college dormitories, prisons, and military barracks in census data (National Research Council, 2006). For my primary results I count all children living in dormitories, prisons and military barracks at ages 22-25 as independents. Appendix Figures A.1 and A.2 compare the estimated slopes and intercepts of mobility gradients in parental income and education for the primary sample and an alternative sample that excludes children in “group living” situations. The results are nearly identical with the one exception of an anomalously flat slope of the schooling-schooling gradient in 1970, which reflects an oddly low level of estimated final schooling among children of high-education parents in that year.

There is substantial variation in the fraction of children with zero or missing values for parental characteristics. Appendix Table A.4 displays this variation for whites and

blacks, restricting to dependent children age 22-25. The fraction of parental education values that are missing is small in all years for both whites and blacks, and the fraction of children with parents reporting highest grade completed of zero is both small and empirically plausible in all years. The fraction of missing parental income observations follows a U-shaped time trend for both whites and blacks, and therefore does not seem likely to explain the observed decline in mobility.

The fraction of children with parents reporting zero income raises more serious concerns, as these shares are very high in 1940 and fall significantly and steadily over time.³¹ However, changes in the composition of families reporting zero income over time are unlikely to be driving the decline in IM for three reasons. First, the pattern is nearly identical for whites and blacks, despite the very large differences in the evolution of their estimated IM. Second, a simple exercise suggests the increase in mobility for whites is too large to be accounted for by the decline in the share of families reporting zero income. Note that the share of families reporting zero income falls by 14 percentage points between 1940 and 1960. Suppose that these 14 percentage points of families are perfectly mobile, in that the slope of their children’s education gradient with respect to parental income is zero. This means that the true 1940 gradient would actually be $(0.14(0) + 0.86(0.4) =) 0.34$, which is still considerably higher than the estimated slope in 1960 of 0.28. Of course this exercise is highly conservative because the additional families reporting zero incomes in 1940 are unlikely to have perfect mobility. Therefore it is unlikely that these families account for a significant share of the observed mobility gains.

9 Model Validation

In Section 4 I discussed three implications of a stylized model used to guide intuitions about the estimated mobility gradients. The first implication is that the intergenerational education elasticity ($\beta_{h_t, h_{t-1}}$) should equal the intergenerational income elasticity (IGE). This implication is approximately borne out in the data, as shown above at the national and state levels. The second implication is that the CEF of children’s human capital with respect to parents’ human capital should be linear. Above in Figure 9.b I presented evidence that this CEF is in fact convex in every year, not linear, as has also been shown for the CEF of children’s income with respect to parental income by Chetty et al. (2014a).

³¹Adults reporting zero income have very similar occupational composition as adults with missing income. Both of these groups are much more likely to report occupation “unclassifiable,” “farmer,” and “proprietor or manager” than adults with positive income.

The third implication is that the two types of schooling gradients I estimate, with respect to parental income and parental schooling, are related to each other in steady state by Equation (15), reproduced here for convenience:

$$\beta_{h_t, \ln y_{t-1}} = - \left(\frac{1}{p} \lambda \sigma_\varepsilon^2 \right) + \frac{1}{p} \cdot \beta_{h_t, h_{t-1}}. \quad (19)$$

One way to exploit this result is to regress estimates of $\beta_{h_t, \ln y_{t-1}}$ on estimates $\beta_{h_t, h_{t-1}}$ in a sample of groups that are in different steady states. Unfortunately, this regression only identifies a fixed intercept and slope in Equation (15) under the strong exclusion restriction that steady state variation in the two gradients stems entirely from θ or γ , rather than variation in p , λ , or σ_ε^2 .

The situation improves slightly if I assume fixed values for the parameters p and σ_ε^2 . Now λ can be allowed to vary across groups along with θ and γ . This assumption implies values for λ and $\theta(1 - \gamma)$ based on variation in gradients across groups in different steady states. I define groups by state of birth and race, controlling for year, and I explore values of $p \in [0.05, 0.25]$. Using census data, I find that σ_ε^2 , the variance of log family earnings conditional on schooling, falls in the range of 0.4-0.6 for all schooling groups over the 1940-2000 period. This range likely overstates σ_ε^2 , which refers to variance in lifetime income, because lifetime income variation tends to be smaller than annual income variation (Aguiar and Bils, 2011). I therefore explore values of $\sigma_\varepsilon^2 \in [0.2, 0.5]$.

These assumptions yield plausible distributions for λ in the range of $[0.2, 1]$. I also find that implied values for $\theta(1 - \gamma)$ are largely negative, implying that either financial investments in human capital are counterproductive ($\theta < 0$), or schooling subsidies have an elasticity less than -1 with respect to parental income ($\gamma > 1$), implying extremely progressive public school finance. Neither of these implications seem plausible for the 1940-2000 period. Perhaps unsurprisingly, a steady state version of this highly stylized model cannot fully account for the estimates. Either the steady state assumption is too strong—which greatly weakens the empirical predictions of the model—or some other assumption is too false.

10 Conclusion

In this paper I develop a new method to estimate intergenerational educational mobility on cross-sectional U.S. census data. The method overcomes the problem that most children cannot be linked to parents by ages of school completion, and thereby allows for estimation of final educational outcomes by parental income and education. I construct

non-parametric final schooling gradients in these parental characteristics and show that some of these gradients are linear. I exploit this linearity to estimate intercepts and slopes as robust measures of absolute and relative IM, respectively, that are comparable over time, places and groups. I use a simple economic model to relate some of these implied mobility statistics to each other and to more traditional measures of IM based on children's earnings and income.

I use this new methodology to document a range of important new historical facts about IM. IM increased dramatically after WWII before stabilizing in the 1960-80 period when panel data sets first become available. This increase in IM was economically large; relative mobility by itself may have increased aggregate annual earnings growth by up to a quarter of a percentage point over the 1940-80 period. The increase in IM was broad-based but slightly larger for men, much larger for blacks, and much larger in the South. The IM disadvantage of the U.S. South in recent decades turns out to be the tip of a much larger historical iceberg.

Turning to causes, I show that the increase in IM likely stemmed from increased high school enrollment, not college enrollment. I show that relative IM in terms of college enrollment has declined since 1940 despite decades of reforms seeking to equalize college access across socioeconomic groups. I calculate IM statistics separately by state of birth and find that various measures of IM positively correlate with higher state income, greater equality, and greater school inputs. Finally, I show that several predictions of the stylized model of borrowing constraints and parental income receive only partial support in the data. In future research, the method developed here can shed new light on IM for subgroups that are too small to examine in panel data, as well as IM across a wider range of countries and time periods than has previously been possible.

ONLINE APPENDICES

A.1 Correction for Transitory Income

Each census only contains one year of parental income per family, potentially leading to biased estimates of parental Engel curves in permanent income due to measurement error. This is a larger problem here because measurement error in permanent income may vary systematically across racial groups, leading to differential mismeasurement of μ_g and θ_g and therefore underestimating the importance of income in explaining group schooling differentials. Recent research, for example, has shown that income may explain a much larger share of black-white test score gaps than previously thought Rothstein and Wozny (2014).

To clarify the problem, let annual income of individual i in group g in year t equal permanent income plus noise

$$y_{igt} = y_{ig} + e_{igt}. \quad (20)$$

Let h_{ig} indicate final schooling for child i in group g . For simplicity I here assume the schooling gradient in question is linear, as I find to be the case for schooling gradients in parental income deciles. I would like to estimate the slope and intercept of the Engel curve with respect to permanent income, separately for each group g :

$$h_{ig} = \theta_g + \beta_g y_{ig} + \varepsilon_{ig} \quad (21)$$

Instead, we are forced to estimate Engel curves using annual income or annual earnings:

$$h_{ig} = \theta_g^* + \beta_g^* y_{igt} + \varepsilon_{ig}^* \quad (22)$$

The relationships between the coefficients in the feasible and the best-case regressions are

$$\begin{aligned} \beta_g^* &= (\alpha_g \lambda_g) \cdot \beta_g \\ \theta_g^* &= \theta_g + (1 - \alpha_g^2 \lambda_g) \mu_g \beta_g \end{aligned} \quad (23)$$

where α_g is the coefficient in a regression of transitory income on permanent income in group g , λ_g is the ratio of permanent to transitory income for group g , and μ_g is average permanent income in group g . The measurement error arises from respondents' recall mistakes, but also from transitory income shocks, lifecycle trends, and non-labor income.

Equation (23) shows that the use of annual rather than permanent income creates two problems. First, if groups differ in permanent income levels μ_g , then lower-income group schooling gradients will be shifted down relative to higher-income group schooling gradients, due to differential mean-reversion. Intuitively, if a black family and a white family are equally poor in a given year, the white family likely has higher income before and after this year than the black family, and therefore higher permanent income and child schooling. Figure A.3 illustrates this problem in the PSID by plotting average percentile in permanent income by annual earnings deciles for black and white families

separately in 1969. At all levels of annual earnings, black families have significantly lower permanent income, with a gap ranging from 5-15 percentiles. This gap arises from both differential non-labor income and differential mean-reversion of transitory shocks.

The second problem highlighted by Equation (23) is that if groups differ in the variance share of transitory income λ_g , then schooling gradients in annual income will have slopes differentially attenuated by measurement error. For example, if black workers are more likely to be laid off, this will flatten the black Engel curve relative to the white Engel curve as estimated in cross-sectional data.

I address these problems directly by estimating the terms in Equation (23).³² A first step is to exploit the focus on parental income percentiles, rather than income levels or logs. This choice mechanically sets $\lambda_g \equiv 1$ if no individuals have identical incomes and incomes are not censored. In practice this is a good approximation in this application. Note that λ_g is less stable over time for income in levels or logs, because income volatility increases over this period as other researchers have documented (e.g., Shin and Solon, 2011). I estimate μ_g in census data for each race in each year as the average percentile of annual parental income, which will equal the average percentile of permanent parental income if transitory and lifetime shocks cancel out within racial groups. The term α_g can be estimated directly in the PSID, but not in the census. If this moment is stable in the PSID, then it suggests extrapolation to earlier census years and to Asians has some credibility. To calculate α_g in the PSID, I regress total family earnings percentile in each year on permanent income percentile, restricting to families with at least 10 years of income in the PSID. Figure A.4 displays α_g for whites and blacks separately in the PSID by year. The moment appears highly stable over time, and roughly similar across races. I therefore estimate this parameter at around 0.8.³³

Implementation

I implement the correction for these permanent income differences using Equation (23). To give a concrete example, the adjustment in 1940 uses the values $\alpha_g = 0.8$ for all races based on Figure A.4, $\lambda_g = 1$ for all races, and $\mu_{white} = 6.6$ and $\mu_{black} = 4.3$ based on average decile of annual total parental earnings in the census. The only thing changing over the years are these average parental earnings deciles.

This adjustment turns out to make little difference to the results, and I therefore do not report the adjusted results. The results are also similar when I estimate the schooling gradients using parental home mortgage and rent expenditures rather than family income, and when I reduce black annual earnings by plausible amounts to reflect permanent income gaps prior to constructing income deciles. It thus appears that unobserved permanent income differences are unlikely to drive the main patterns documented above.

³²I experimented with using home values and rents as measures of permanent income. These measures are appealing because they exist in census data for all races. However, home values and rents do not predict permanent income percentile as well as annual income or earnings percentiles in PSID data. In practice none of these choices affect the main results of the paper.

³³Haider and Solon (2006) show this parameter in individual earnings regressions will not generally equal 1 under realistic lifecycle earnings processes.

Table 1: Tests for Parallel Schooling Trends in Parental Income

Notes: Table documents that dependent status primarily alters level of children's schooling, not slope with respect to parental group status. Displays estimates of equation (5) by subsample for parental income groups. Columns (1)-(9) use the PSID, column (10) uses children from the NLSY79. Parental characteristics measured when children are age 17. Children's schooling at ages 23-25 is set to missing when lower than six years. Children with zero parental income at age 17 excluded. Income deciles calculated separately by year. Sample weights used in construction of deciles and in regressions.

Table 2: Tests for Parallel Schooling Trends in Parental Education

Notes: Table documents that dependent status primarily alters level of children's schooling, not slope with respect to parental group status. Displays estimates of equation (5) by subsample for parental education groups. Columns (1)-(9) use the PSID, columns (10)-(14) use children from the NLSY79, the General Social Survey, and Occupational Change in a Generation 1973 and 1962 samples, respectively. Note that PSID and NLSY are based on parental self-reported characteristics, while GSS and OCG are based on children's recalled parental education. Parental characteristics measured when children are age 17 in PSID and NLSY, at 16 in GSS and OCG data. Children's schooling at ages 23-25 is set to missing when lower than six years. Parental schooling set to missing if under 10 years. Sample weights used in construction of collapsed data but not in regressions, in order to correspond more closely to Figure 3.

Table 3: Validation of Group Cohort Size Predictors: Parental Income Groups

Notes: Documents ability to predict group cohort sizes at later ages with group cohort sizes at earlier ages. Columns (1)-(3) regress actual parental income group cohort shares at ages 12-15 on predicted parental income group cohort shares at ages 12-15 and a constant, where each column uses a different predictor. Columns (4)-(10) run the regression in Column (1) separately by census year 1940-2000. Regressions for white-only sample. All regressions weighted by the square root of the cell size.

Table 9: Mobility Estimates for Education Ranks in Parental Income and Education Ranks

Notes: Displays estimated intercepts and slopes of children's schooling rank gradients with respect to parental income and education ranks. All ranks here on scale from 0 to 100. Ranks computed on full population for each age and year, ignoring incomes of zero in the parental income rank, and assigning ranks as midpoints on intervals with ties. Estimates correspond to α_t and β_t from Equation (16). Regressions weighted by square root of estimated cell sizes.

Table 10: Correlations of Mobility with State Characteristics, 1940-2000

Notes: Restricting to whites. Table displays bivariate correlations of mobility statistics listed in row titles for state-of-birth by year cells with characteristics listed in column titles for state-of-residence by year cells from the previous census when children would have been 12-15 years old. Correlations constructed using residuals of all variables from regressions on full set of region by year dummies, using four regions based on census definitions. Correlations restricted to intercepts and slopes estimated in regressions with $R^2 \geq 0.5$, and with full coverage over parental income and education groups. Parental education groups defined as highest grade attained range 6.5-17 of household head. Parental income groups defined as total parental earnings decile, excluding households with zero parental earnings. Variables in column headings defined as follows. “p75-p25” defined as difference between 75th and 25 percentiles of log total parental earnings distribution. “Dropout age” refers to minimum school dropout age. Relative teacher pay refers to the ratio of the average public teacher salary in a state to the average salary of non-teacher college-educated workers in that state. “ln(Income)” refers to average of the log of the sum of husband’s and wife’s earnings. Income data are calculated from the census for household heads aged 40-55 in years 1940-2000, and for 1930 are taken from “State Personal Income 1929-99 CD-ROM” (U.S. Department of Commerce, Bureau of Economic Analysis) as displayed in (Garret and Wheelock, 2005). “Teen birth rate” defined as mean of dummy for any children for girls age 15-19 in census data. “Share black” refers to share black of all state residents in census data. Note p75-p25 in 1940 is matched to the year when children would have been 22-25 years old, rather than 12-15, due to the lack of state-level income inequality measures prior to 1940. Sample sizes smaller for dropout age, class size, and relative teacher pay because these variables were taken from Stephens and Yang (2014) and were not available for the full 1940-2000 period.

Table 12: Returns to Schooling by Parental Group and Child Outcome Gradients in OCG

Notes: Documents shared returns to schooling across father's education groups, and children's schooling and log earnings gradients in father's education, together suggesting that educational mobility gains likely increased income mobility gains. Displays various regressions on OCG1962 and OCG1973 data. Columns (1)-(5) assess whether the returns to schooling differ by parental background. Columns (6)-(9) assess whether changes in mobility can be observed directly in OCG data. All regressions restricted to whites. Underlying data collapsed prior to regression to child's education by father's education by cohort cells in columns (1)-(5) and to father's education by cohort level in columns (6)-(9). Sample weights used in collapse but not in regressions. Note father's education can take on any integer values between 7 and 17 in OCG1973 sample, but can only take on values of 8, 10, 12, 14, 16 in OCG1962. Columns (1)-(5) regress log of earnings on years of schooling, father's education, and the interaction of these two variables, separately for each 10-year birth cohort and OCG data set. Columns (6) and (7) regress education and log of earnings, respectively, on father's education, 10-year cohort dummies, and the interaction of these two variables in the OCG73 data. Columns (8) and (9) repeat the exercise in columns (6) and (7), respectively, on the OCG62 data.

Table A.4: Percent of Children with Missing and Zero Values for Parental Characteristics, by Year and Race

Notes: Sample restricted to children living with parents age 22-25 in census data.

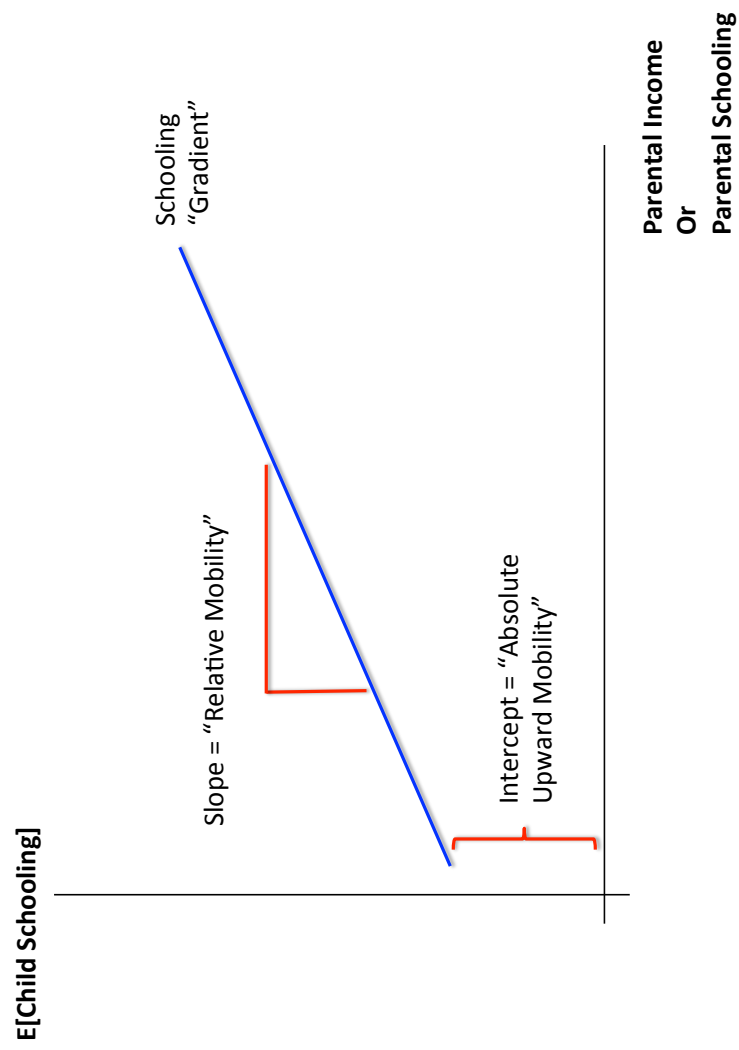

Figure 1: Illustration of Schooling Gradient and IM Statistics

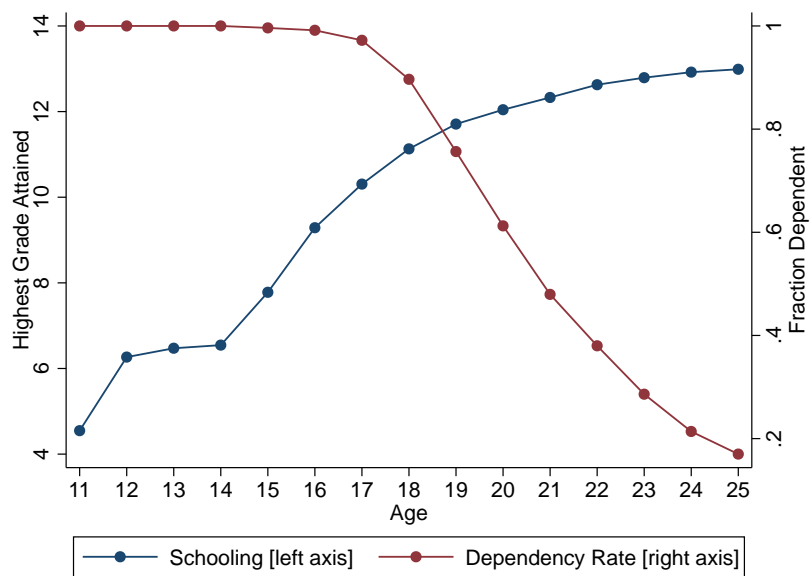

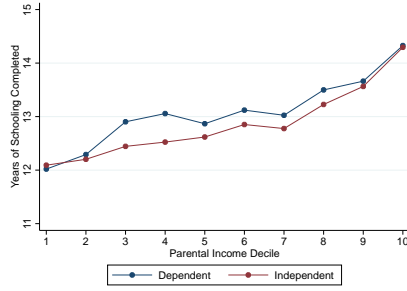

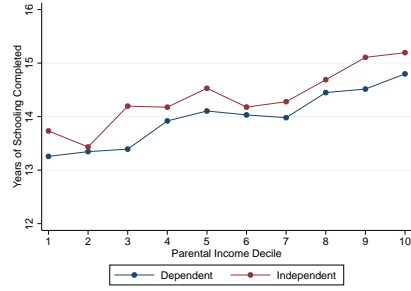

Figure 2: Schooling and Dependency Status by Age in 1980

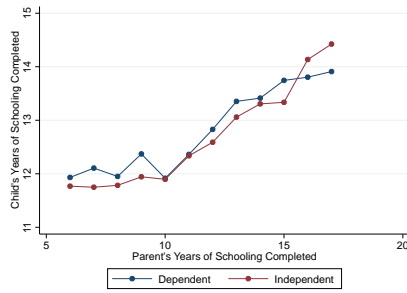

Notes: Red line plots fraction of native-born children living with parents by age in 1980. Blue line plots average schooling of native-born children by age in 1980. Whites only, excluding Alaska and Hawaii.

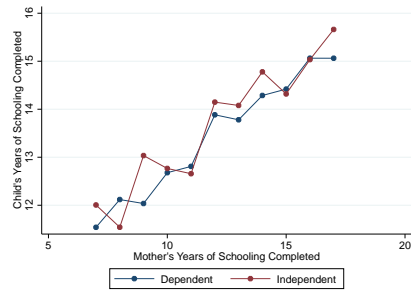

(a) Gradient in Parental Income, PSID

(b) Gradient in Parental Income, NLSY79

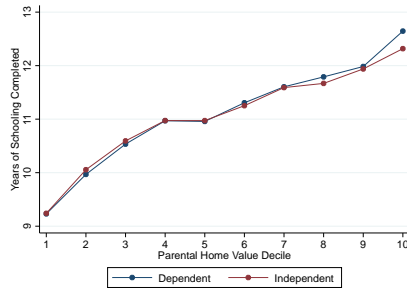

(c) Gradient in Parental Education, PSID

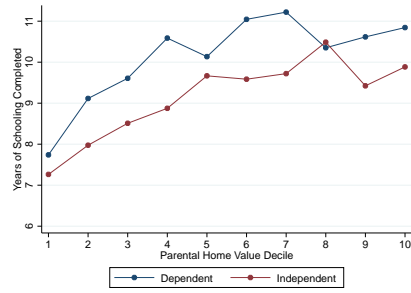

(d) Gradient in Parental Education, NLSY79

Figure 3: Highest Grade Attained at Ages 22-25 by Parental Characteristics at Age 17

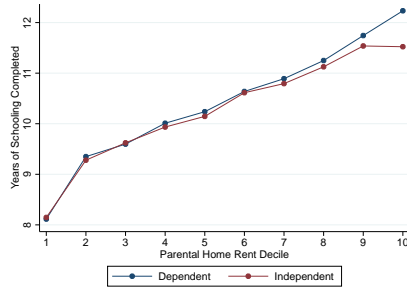

Notes: Figures based on data from PSID and NLSY79, pooling years 1968-2011 and 1994-2010, respectively. Parental characteristics measured when children are age 17. Children's schooling at ages 22-25 is set to missing when lower than six years. Children with zero parental income at age 17 excluded. Income deciles calculated separately by year. Sample weights used in all calculations.

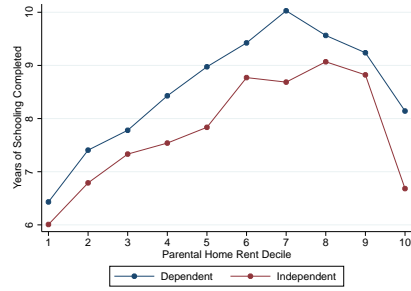

(a) Schooling by Parental Home Values, Whites

(b) Schooling by Parental Home Values, Blacks

(c) Schooling by Parental Rents, Whites

(d) Schooling by Parental Rents, Blacks

Figure 4: Final Schooling at Ages 22-25 in 1940 by Parental Group Status

Notes: Figures plot highest grade attained for ages 22-25 by parental home value or rent deciles based on matched 1930-1940 census data. Families with zero rent and earnings in 1930 excluded. Underlying data count each cohort aged 22-25 in 1940 equally for each parental group. Deciles calculated on full population of parents with any children age 10-17 in 1930, including all non-farm owner-occupied or renter-occupied units, weighting by number of children.

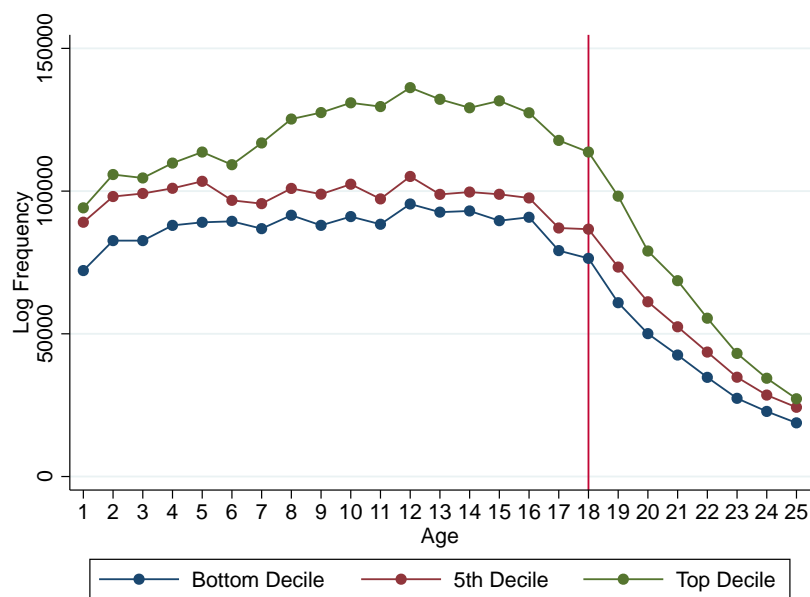

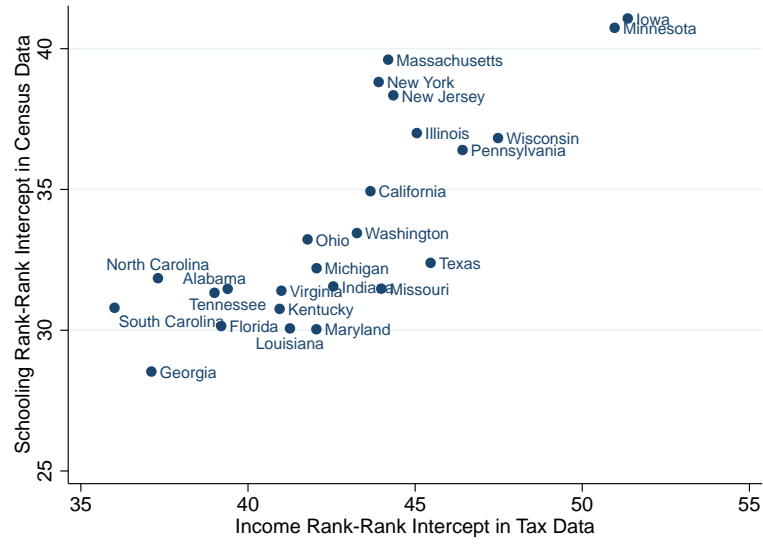

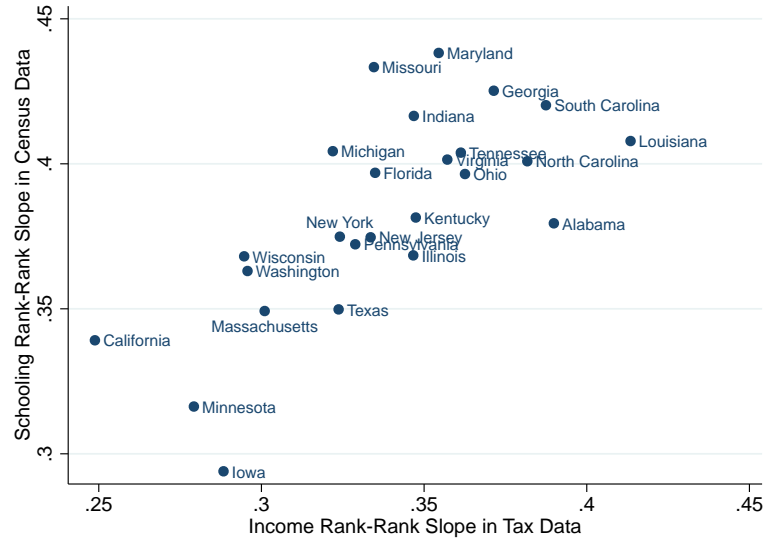

Figure 5: Number of Dependent Children by Age for Parental Income Decile Groups, 1940

Notes: Figures plot frequencies for white native-born children living with parents by age and race in 1940 100% IPUMS data sample.

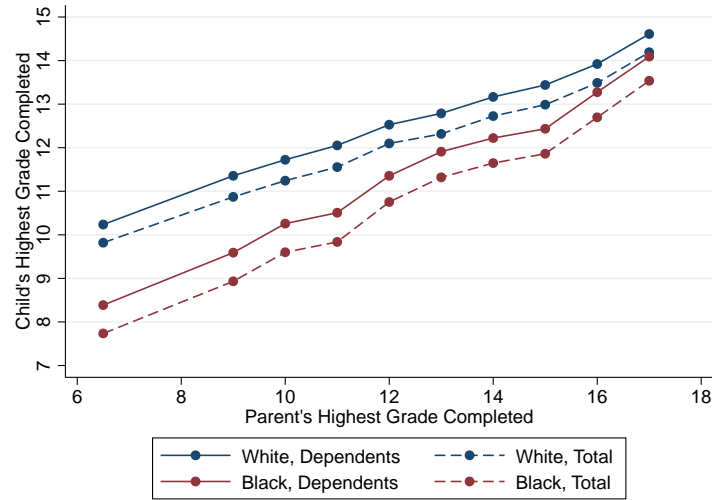

(a) Absolute Upward Mobility

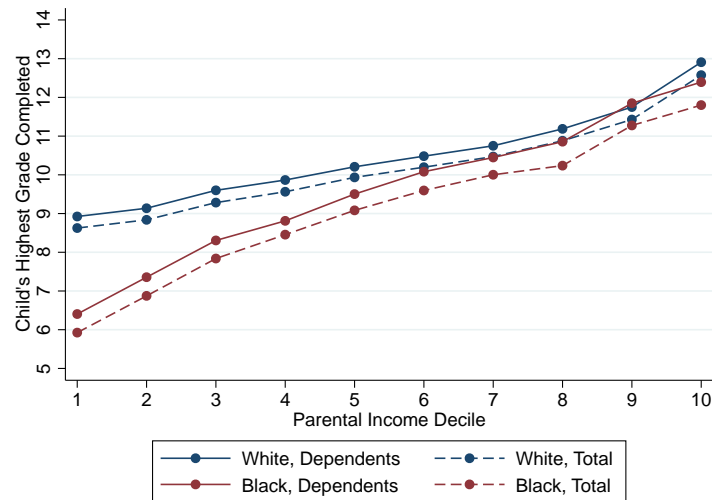

(b) Relative Mobility

Figure 6: Comparison of Mobility Estimates by State in Census and Tax Data, 2000

Notes: Panel (A) plots intercepts from regression of child education rank on parental education rank in census data with adjustment for independents, against intercepts from regression of child income rank on parental income rank in U.S. population tax records. Panel (B) plots slopes from the same regressions. All races pooled. Education measured as highest grade attained. Education ranks computed on national sample for each age and year separately with midpoints of rank intervals assigned to mass points. Children's education measured at ages 22-25. Restricts to 25 largest states in terms of estimated total number of children age 22-25 in census, where estimation imputes cohort as number of 17 year-olds. Census regression pools data from 1980, 1990 and 2000 censuses. Description of income rank-rank mobility estimates available in Chetty et al. (2014a).

(a) Gradient in Parental Education, Before and After Adjustment

(b) Gradient in Parental Income Decile, Before and After Adjustment

Figure 7: Final Schooling Attainment at ages 22-25 by Parental Group Status, 1940

Notes: Figure plots estimated final schooling pooling separate estimates for ages 22-25, using the correction for independent children described in the text. Uncorrected estimates restrict to dependent children who can be linked with parents directly. Hawaii and Alaska excluded.

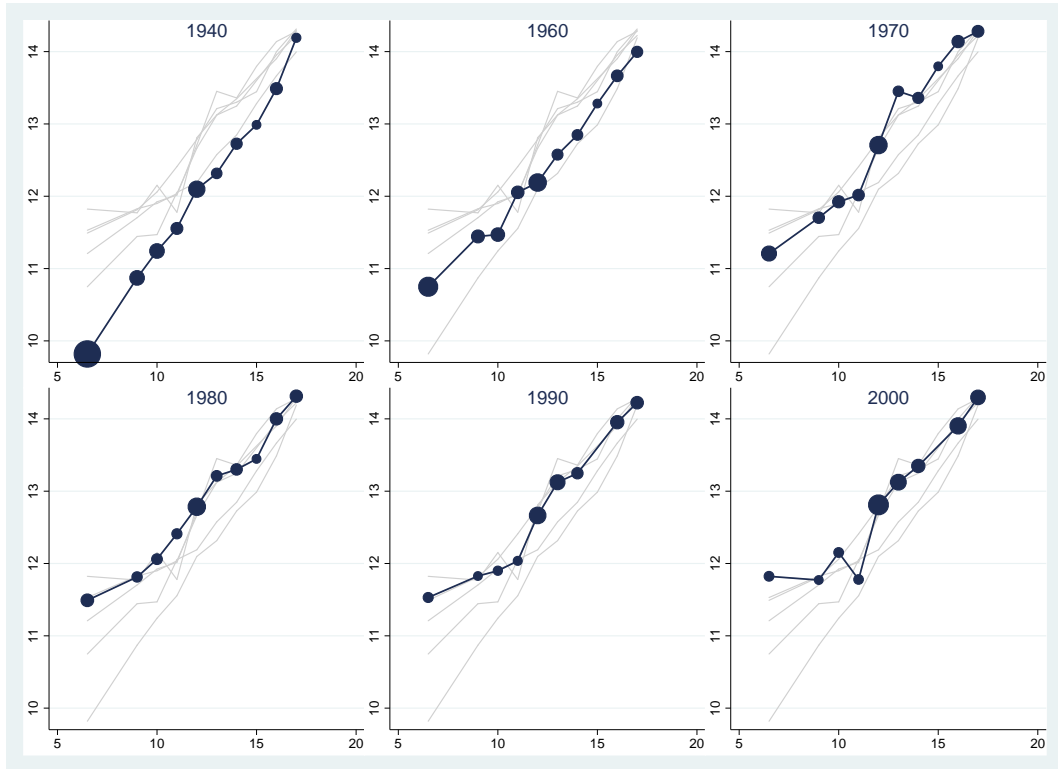

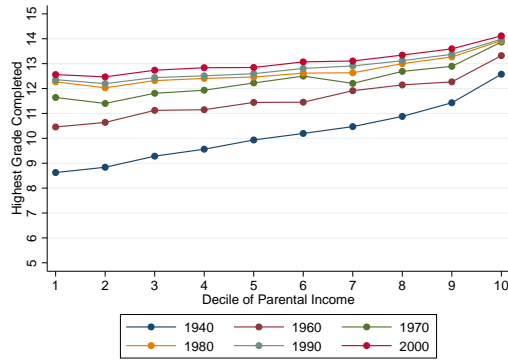

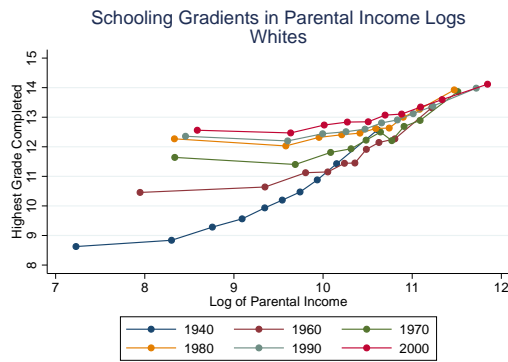

Figure 8: Final Schooling Attainment by Parental Schooling Attainment, 1940-2000

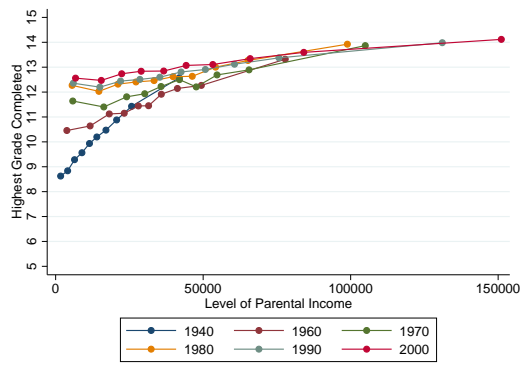

Notes: Figures plot highest grade attained by parental highest grade attained for whites age 22-25, by year. Figure adjusts for independent children as described in text.

(a) Decile of Parental Income

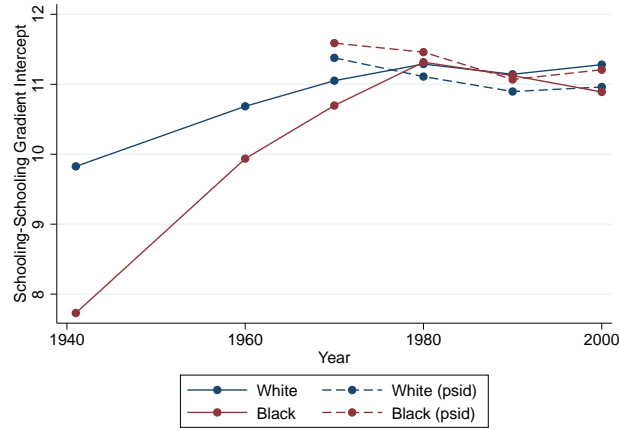

(b) Log of Parental Income

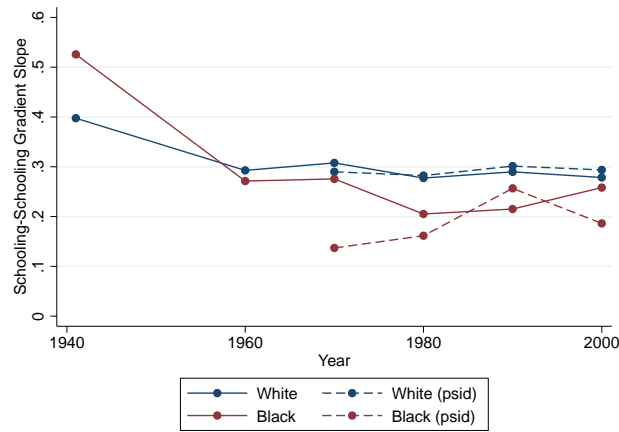

(c) Level of Parental Income

Figure 9: Final Schooling Attainment by Parental Income, 1940-2000

Notes: Figure adjusts for independent children and pools ages 22-25 as described in text. Parental income calculated as sum of head and spouse. Parents restricted to ages 25-65. Hawaii and Alaska excluded.

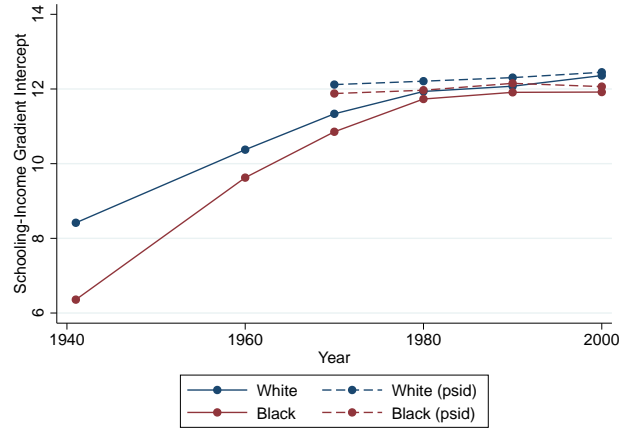

(a) Intercepts = Absolute Upward Mobility

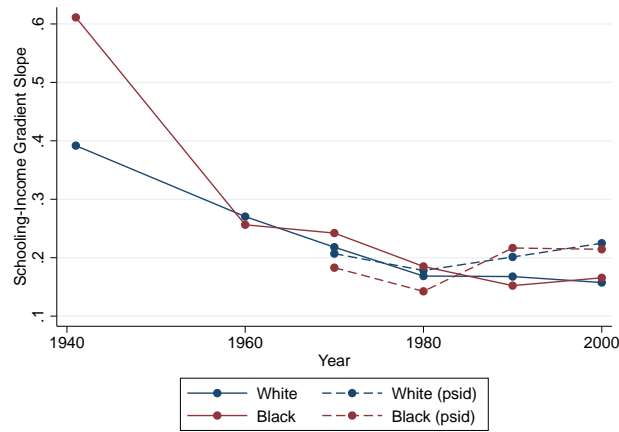

(b) Slopes = Relative Mobility

Figure 10: Intercepts and Slopes of Linear Schooling Gradients in Parental Education by Race and Year

Notes: Presents estimated intercepts and slopes from linear regressions of children's highest grade attained on parent's highest grade attained, using data grouped at the year by race by parental education level. Sample weights are used to construct cell means, and regressions on collapsed data are weighted by the square of cell size.

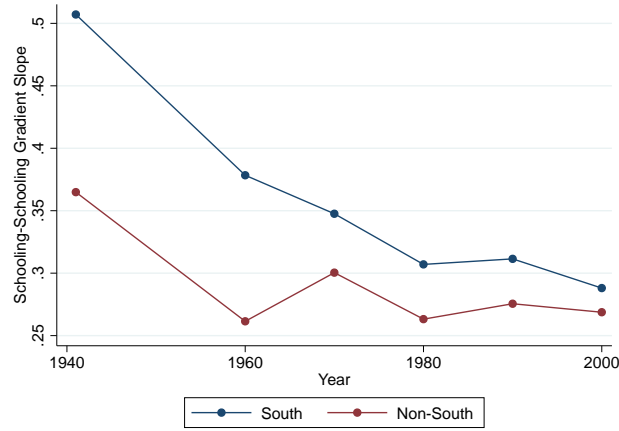

(a) Intercepts = Absolute Upward Mobility

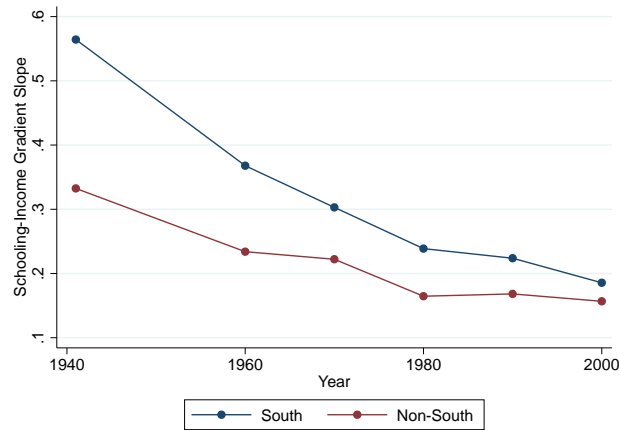

(b) Slopes = Relative Mobility

Figure 11: Intercepts and Slopes of Linear Schooling Gradients in Parental Income Deciles by Race and Year

Notes: Presents estimated intercepts and slopes from linear regressions of children's highest grade attained on parental income decile, using data grouped at the year by race by parental income decile level. Sample weights are used to construct cell means, and regressions on collapsed data are weighted by the square of cell size.

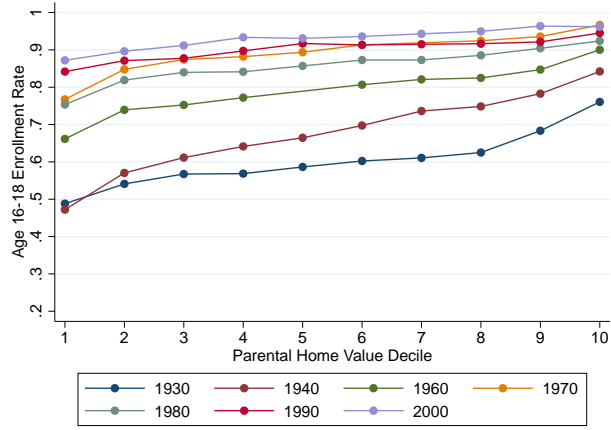

(a) Slopes of Schooling-Schooling Gradients

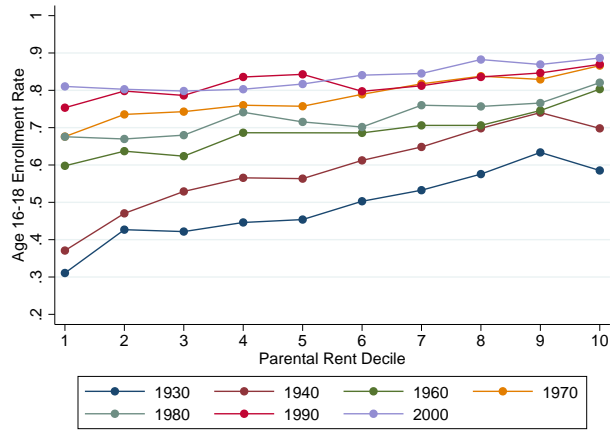

(b) Slopes of Schooling-Income Gradients

Figure 12: Slopes of Linear Schooling Gradients in South and Non-South

Notes: Restricting to whites. Presents estimated slopes from linear regressions of children's highest grade attained on parental highest grade attained or income decile, using data grouped at the year by race by parental income decile level. Adjustment for independent children ages 22-25 as described in text. Sample weights are used to construct cell means, and regressions on collapsed data are weighted by the square of cell size. Estimates correspond to slope estimates in Columns (4)-(5) in Tables 5 and 6.

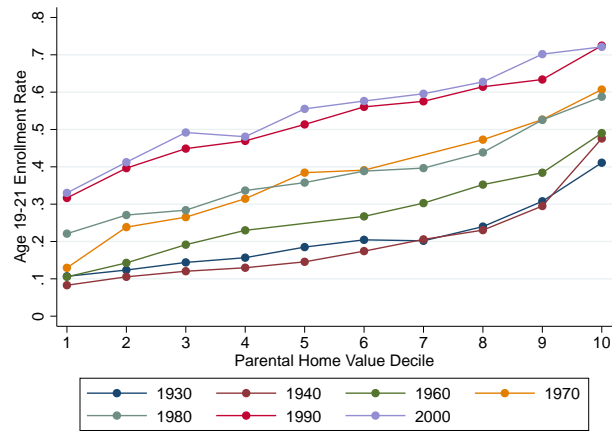

(a) Enrollment by Parental Home Value Deciles

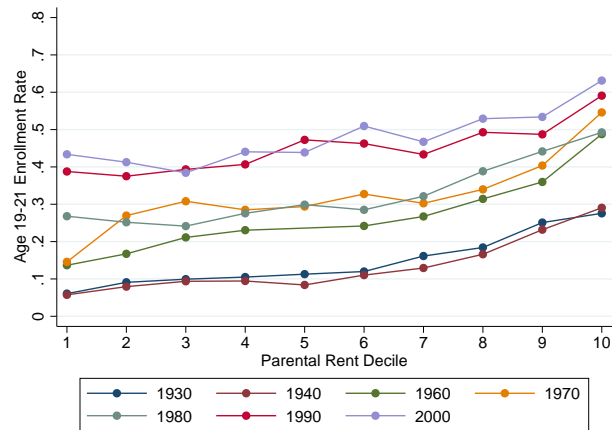

(b) Enrollment by Parental Rent Deciles

Figure 13: High School Enrollment by Parental Home Value and Rent Deciles, 1930-2000

Notes: Restricting to whites. Plots average enrollment for dependent children ages 16-18 by parental home value and rent deciles, by year. Sample weights are used to construct cell means.

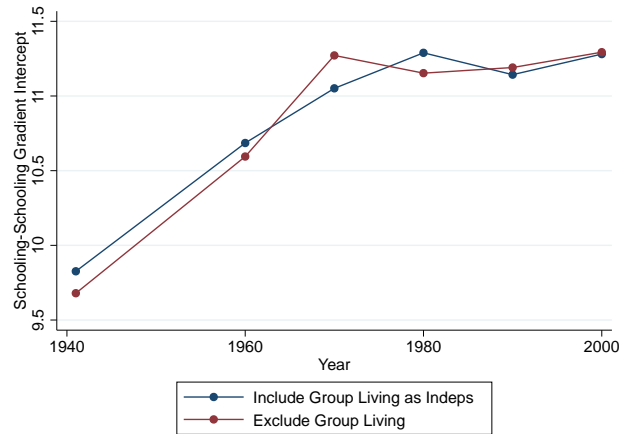

(a) Enrollment by Parental Home Value Deciles

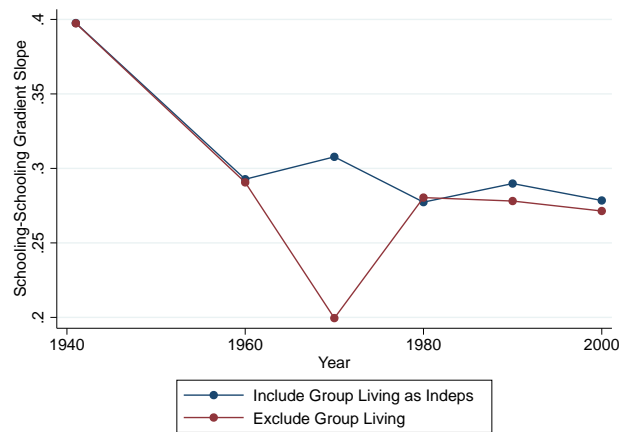

(b) Enrollment by Parental Rent Deciles

Figure 14: College Enrollment by Parental Home Value and Rent Deciles, 1930-2000

Notes: Restricting to whites. Plots average enrollment for ages 19-21 by parental home value and rent deciles, by year. Adjustment for independent children as described in text. Sample weights are used to construct cell means.

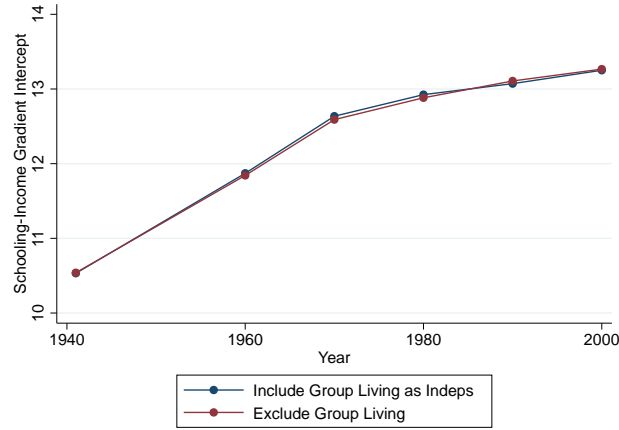

(a) Intercepts = Absolute Upward Mobility

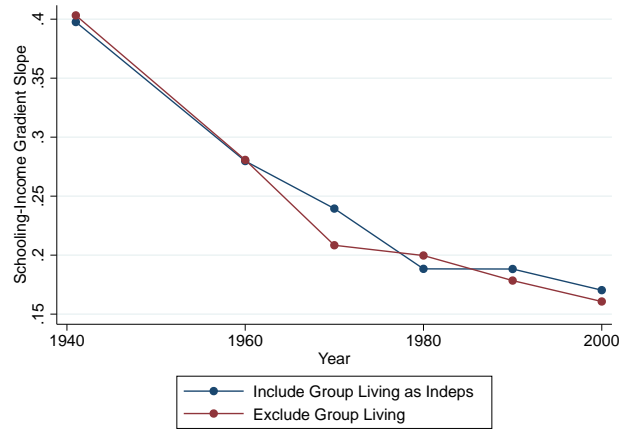

(b) Slopes = Relative Mobility

Figure A.1: Intercepts and Slopes of Linear Schooling Gradients in Parental Education by Sample and Year

Notes: Presents estimated intercepts and slopes from linear regressions of children's highest grade attained on parent's highest grade attained, using data grouped at the year by race by parental education level. Sample weights are used to construct cell means, and regressions on collapsed data are weighted by the square of cell size.

(a) Intercepts = Absolute Upward Mobility

(b) Slopes = Relative Mobility

Figure A.2: Intercepts and Slopes of Linear Schooling Gradients in Parental Income Deciles by Sample and Year

Notes: Presents estimated intercepts and slopes from linear regressions of children's highest grade attained on parental income decile, using data grouped at the year by race by parental income decile level. Sample weights are used to construct cell means, and regressions on collapsed data are weighted by the square of cell size.

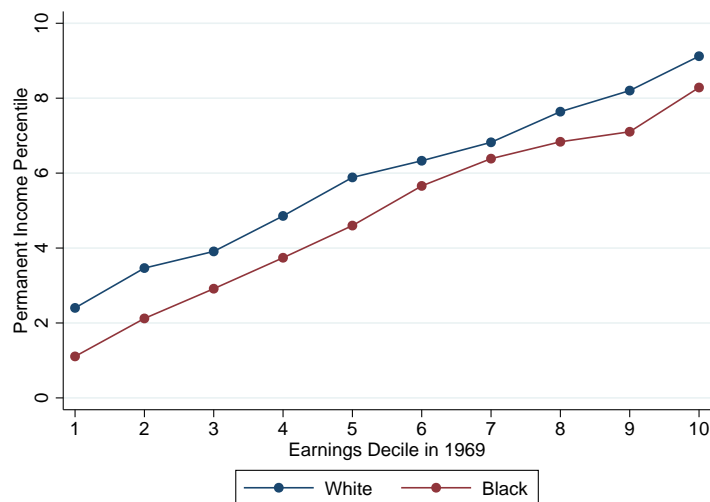

Figure A.3: Average Permanent Income Percentile by Annual Earnings Percentile in 1969

Notes: Sample includes household heads, ages 25-65. Income includes labor, business, transfer, interest, dividends, and other sources of total family income. Permanent income calculated by averaging annual income in all available years for each individual household head, then taking the log of this average. Annual earnings deciles constructed using 1970 survey sample weights. Zeros excluded from annual earnings deciles, but included in construction of permanent income.

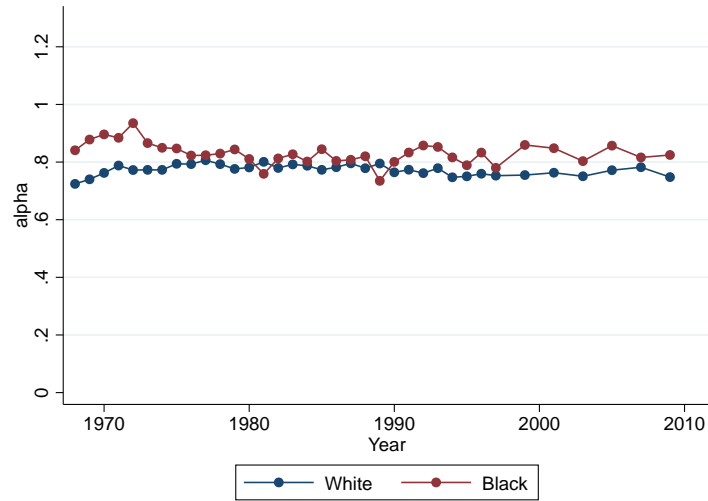

Figure A.4: Estimated α_g by Year

Notes: The term α_g represents the coefficient from a regression of annual total family earnings percentile on permanent total family income percentile, run separately on each year in the PSID using each year's PSID probability weights. Sample includes families with heads between ages 25-65. Income includes labor, business, transfer, interest, dividends, and other sources of total family income. Permanent income calculated by averaging annual income in all available years for each individual household head, then taking the log of this average. Annual earnings deciles constructed using each year's sample weights. Zeros excluded from annual earnings percentiles. Zeros included in construction of permanent income from annual incomes, and in construction of permanent income percentiles.
