ABSTRACT

Firms facing complex objectives often decompose the problems they face, delegating different parts of the decision to distinct sub-units. Using comprehensive data and internal models from a large U.S. airline, we establish that airline pricing is not well approximated by a model of the firm as a unitary decision-maker. We show that observed prices, however, can be rationalized by accounting for organizational structure and for the decisions by departments that are tasked with supplying inputs to the observed pricing heuristic. Simulating the prices the firm would charge if it were a rational, unitary decision-maker results in lower welfare than we estimate under observed practices. Finally, we discuss why counterfactual estimates of welfare and market power may be biased if prices are set through decomposition, but we instead assume that they are set by unitary decision-makers.

1 Introduction

Firms face many complex decisions. Naturally, some are complex because they are ill-structured or arise only once. Other decisions can be complex even if they are cleanly structured and arise routinely. Confronted with a complex decision, a manager might consider two approaches. First, they might apply a heuristic that does not use all available information to solve the problem (e.g., Simon, 1956). Alternatively, they might decompose the problem, delegating different parts of the decision to different sub-units (e.g., Radner, 1993). However, this delegation of decision rights creates the potential for coordination failures, and, if sub-units also rely on heuristics, this may cause decisions to differ significantly from those commonly used to study firm behavior. There may also be significant consequences for efficiency and welfare.

In this paper, we demonstrate the importance of organizational structure and the use of heuristics in understanding firm pricing behavior. Using granular data and internal models from a large U.S. airline, we show that pricing is subject to important biases, including: relying on a heuristic that does not internalize product substitution of any kind, using persistently biased forecasts, and pricing on the inelastic side of internally estimated demand curves.¹ However, we show that prices can be explained by accounting for organizational structure and for the decisions made by the multiple departments that are tasked with supplying inputs to the observed pricing heuristic. Given other departments' heuristic inputs, providing biased inputs is revenue maximizing for the firm. In other words, department managers choose inputs in a boundedly rational way given their delegated decision rights and the complex interactions of department input decisions in the pricing heuristic (Simon, 1956, 1962). There are substantial welfare consequences from prices being set through such decomposed decision-making. Simulating the prices the firm would charge if it were a rational, unitary decision-maker results in lower welfare than we estimate under observed practices due to increased price targeting. We discuss why counterfactual estimates of welfare and market power may be biased if we assume prices are set by a unitary, rational decision-maker when they are in fact set through decomposition.

Following deregulation, airlines adopted pricing heuristics that relied on decentralized decision-

¹We use the term heuristic instead of algorithm throughout to emphasize that the heuristic used by the firm does not solve an economic model.

making by individual departments.² In the observed organizational structure, the “network planning department” decides where to fly and assigns initial capacities. Given the network, the “pricing department” designs itineraries and chooses a menu of discrete fares that consumers may face. Finally, the “revenue management department” (RM) is responsible for estimating demand, developing flight forecasts, and monitoring flight-level performance. These inputs are then given to the observed pricing heuristic that decides how many seats it is willing to sell at each fare level. For a fictional example, the network planning department might decide to fly twice a day from London to Paris, once in the morning and once in the afternoon, and sets the size of the plane for each flight. The pricing department might decide that there are three economy fare levels, say \$200, \$150, and \$100, for each flight. The revenue management department, using an estimate of the demand curve for each flight, develops a demand forecast for each of the three fare values. These inputs—the capacity decisions, the fare menus, and the forecasts—are given to the heuristic, which allocates remaining seats to each fare.

While we directly observe the separation of pricing responsibilities for the large U.S. airline that we study, we confirm that this organizational structure is also used widely by other firms solving complex pricing problems. Analyzing online job listings and professional network profiles, we show that some ultra low-cost carriers, recently founded airlines, and all major airlines maintain separate pricing and RM departments. Moreover, cruises, hotels, car rentals, trains, and rideshare companies have the same organizational structure and department responsibilities. We believe that our approach, analysis, and results apply more widely across many important sectors of the economy.

Our study leverages comprehensive data from a large U.S. airline. In addition to observing daily prices and quantities, we observe all department decisions, including capacity choices, fare decisions, the internal demand model, demand estimates, flight-level forecasts, and the pricing heuristic’s exact design (code). We also observe all consumer interactions (clicks) on the airline’s website. Our sample covers 300,000 flights and 470 domestic routes over two years.

We document three important facts using the data and internal models used by the firm.

²We do not observe decisions being delegated to a single subordinate (e.g., Aghion and Tirole, 1997). The organizational structure also possesses similarities to more recent theoretical work in organizational economics that analyze decentralized decision-making (e.g., Alonso, Dessein and Matouschek, 2008; Rantakari, 2008; Dessein, Galeotti and Santos, 2016).

First, we describe the pricing heuristic used by the firm and show that observed pricing rules differ from the empirical literature that studies pricing through the lens of optimal dynamic unitary decision-making.³ In particular, the heuristic does not solve a dynamic program. Instead, it is myopic and considers the same static allocation problem every day. It abstracts from all forms of substitution, including across cabins within a flight, flights within a day, departure dates, and competitor options.⁴ Every flight is optimized using the same heuristic, regardless of market structure.

Second, we show that department input decisions are biased and subject to miscoordination. For example, the RM department relies on the same single-product demand model for all routes, despite significant differences in competition and the number of flights per day. We show that departments do not internalize all of the decisions made by other departments, leading to input decisions that are “incompatible.” We show that the pricing department frequently chooses fares that are on the inelastic side of the RM department’s demand model. We explain why this leads the heuristic to frequently offer consumers “inelastic” prices.

Third, we show that departments manipulate the inputs they supply to the pricing heuristic. These actions are consistent with manipulating information in behavioral theories of the firm (Cyert and March, 1963). For example, we show that RM analysts inflate the demand model, causing 93% of flights to be over-forecasted when supplied to the heuristic. These actions are consistent with several potential behavioral explanations, including overconfidence and misreaction to information (e.g., Camerer and Lovallo, 1999; Bordalo et al., 2020; Ma et al., 2020). These actions are also consistent with using a workaround or “kludge” (Ely, 2011) to address a known issue with the heuristic—that it can deflate opportunity costs of capacity due to its design (Wollmer, 1992; Brumelle and McGill, 1993; Cooper, Homem-de Mello and Kleywegt, 2006).⁵ We estimate that analysts over-forecasting demand reduces the percentage of flights that are priced on the inelastic side of the internal demand model by up to 60%.⁶

³For examples, see Sweeting (2012); Cho et al. (2018); Williams (2022); Aryal, Murry and Williams (2022); Pan and Wang (2022).

⁴This can affect what inferences can be made about market conditions. For related theoretical work, see, e.g., Bohren (2016) and Heidhues, Kőszegi and Strack (2018).

⁵According to Ely (2011), “A kludge is a marginal adaptation that compensates for, but does not eliminate, fundamental design inefficiencies.”

⁶There may also be competitive reasons to bias forecasts. Berman and Heller (2020) present a theory on why

These facts are central to how we study delegated decision-making and the use of a pricing heuristic. While we observe a great deal about pricing decisions, we do not directly observe consumer preferences. We do not use the RM department’s single-product demand model to inform consumer preferences due to its inflexibility in capturing demand heterogeneity within and across routes, e.g., the model assumes that demand does not depend on the departure date. Instead, we estimate a flexible demand model for air travel using a recently proposed methodology (Hortaçsu et al., 2023). We use these estimates to simulate demand and measure welfare in counterfactuals.

In the demand model, “leisure” and “business” travelers arrive according to time-varying Poisson distributions. Conditional on arrival, consumers solve a standard discrete choice problem. We provide new descriptive evidence that supports our modeling assumptions. Our model allows for endogenous prices, and we address the challenge of separably identifying preferences from aggregate demand uncertainty by leveraging arrivals and bookings data. We show that our demand estimates are robust to both the choice of instruments and the choice of hyperparameters that account for unobserved arrivals. In total, we estimate 235,000 demand parameters across 140 routes. We find substantial variation in willingness to pay within and across routes. We estimate that business consumers are on average five times less price sensitive than leisure consumers. Average elasticities are -1.1 ($SD=0.6$).

Next, we present our model of supply. Fully endogenizing department decisions is difficult because we do not observe incentive structures. Moreover, departments make many decisions—50 million department inputs are provided to the heuristic each day for the routes in our sample. We simplify our analysis by considering specific unilateral department adjustments to observed inputs. In addition, we do not endogenize capacity decisions. Later, we discuss implications for our results. We compare market outcomes using observed inputs supplied to the heuristic to unilateral deviations in one department’s decisions, holding all other decisions fixed. For deviations, we consider the scenario where the pricing department removes fares that guarantee that the heuristic will never offer “inelastic” prices. We also consider the scenario where the RM department reduces the persistent upward bias in their demand forecasts.

biases can persist, including underestimating price elasticities, in a model of competition.

We present two main findings. First, we show that these unilateral deviations do not increase revenues. Among the deviations considered, miscoordinated and biased inputs are revenue maximizing for the firm. This result is economically important, as it establishes that pricing biases can be explained by accounting for organizational structure and the use of simplifying heuristics, whereas existing work has attributed bias to behavioral frictions, mistakes (e.g., Levitt, 2016; DellaVigna and Gentzkow, 2019; Dubé and Misra, 2021), or a misalignment of incentives within the organization (Atkin et al., 2017; Sacarny, 2018). Although we find no revenue-increasing unilateral deviations from decreasing input bias, we find small gains under extreme biases, e.g., a 1% revenue increase if the RM department overstated their forecasts by 100%.

Our second main finding is that observed prices are inconsistent with a model of the firm as a unitary, rational decision-maker. More precisely, given our demand estimates, we simulate the prices the firm would charge if it solved a dynamic program as a single entity. We limit our analysis to a subset of routes due to the intractability of solving dynamic programs for the airline’s larger routes. We find that observed prices differ substantially from those implied under dynamic pricing. Dynamic pricing results in increased price targeting and lower welfare (by 11%) compared to prices set under observed practices. If the firm solved a dynamic program as a unitary decision-maker, leisure consumers would benefit, and business consumers would be made worse off.

Finally, we review our findings and discuss how our insights can be used to study firm pricing more broadly. We provide novel empirical evidence using internal data and models from a large U.S. firm to highlight the complexity, constraints (Siggelkow, 2001), and consequential simplifications imposed in pricing decisions. We contribute to a small but growing literature on the consequences of firm behavior under biased beliefs or bounded rationality (e.g., Cho and Rust, 2010; Brown, Camerer and Lovallo, 2013; Goldfarb and Xiao, 2011, 2016; Aguirregabiria and Magesan, 2020). We offer the first direct empirical quantification on the differences between internal firm pricing practices and what Rust (2019) describes as the questionable yet maintained assumption that firms behave “as if” they have solved the dynamic problems they face. We highlight that welfare estimates and measurements of market power are sensitive to the

assumptions to how we model supply. In our context, the firm does not internalize static (e.g., product substitution) and dynamic (e.g., scarcity) opportunity costs as commonly assumed in empirical work (for an overview, see Aguirregabiria, Collard-Wexler and Ryan, 2021). If prices are generally set through decomposition and involve heuristics—as we observe at a sophisticated firm—failing to account for coordination failures and consequential simplifications made in practice can lead to misinterpreting observed outcomes and incorrectly simulating counterfactuals.

The paper is organized as follows. In Section 2, we discuss industry pricing practices and detail the pricing heuristic used by the firm. We discuss the data in Section 3 and pricing biases in Section 4. We present the demand model, estimation details, and parameter estimates in Section 5. We investigate department decisions in Section 6. We consider dynamic pricing in Section 7. The conclusion follows.

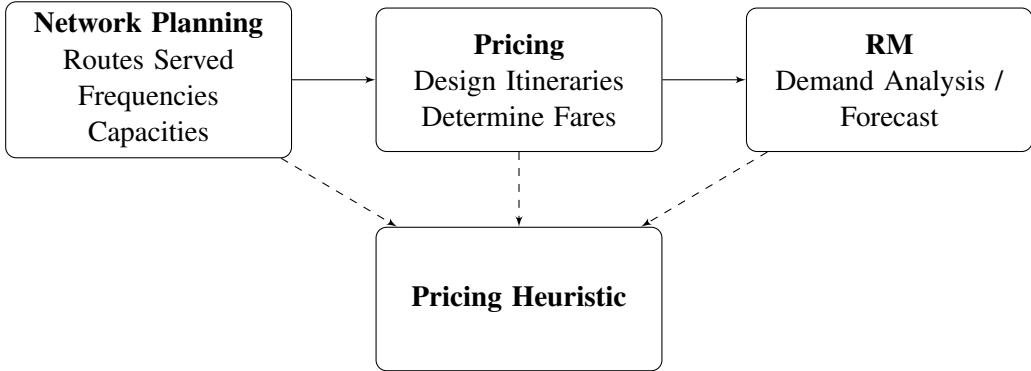

2 Organizational Structure and Pricing Heuristic

We study the U.S. airline industry, which directly supports over 2.2 million jobs and contributes over \$267 billion to the U.S. economy (IATA, 2019). We briefly describe airline pricing practices. Vinod (2021) provides a detailed, historical account.

Prior to the deregulation of the airline industry, the networks and fares of airlines were federally controlled. At that time, pricing was not automated, and airlines physically posted the fares they offered. Post-deregulation, competition intensified, which resulted in airlines lowering fares, particularly for consumers who shopped early. These were the first advance purchase (AP) fares that are now common in advance purchase markets.

In 1972, the U.K.-based airline BOAC developed the first tractable inventory management system that controlled how many discounted fares to offer based on expected demand. American Airlines further developed this optimization tool as computing power increased (Vinod, 2021). The adoption of inventory management tools resulted in a bifurcation of pricing responsibilities, with one department designing the itineraries consumers can purchase and another department monitoring and managing flight-level performance.

Figure I: Division Responsibilities at all Airlines

Note: The figure depicts the key departments and responsibilities at all airlines. The solid arrows show the flow of decisions across departments. The dashed arrows show the departments that influence the heuristic.

Figure I depicts the organizational structure we study. First, the network planning department decides routes served, flight frequencies, and capacities. We do not endogenize these decisions in our analysis and discuss their implications in Section 7. The schedule is passed to the pricing department, which is tasked with designing the itineraries that can be purchased. This includes choosing a discrete menu of fares and fare restrictions, including any AP requirements, for every itinerary.⁷ AP requirements establish the minimum price that can be offered at any point in time and are effective for segmenting customer demand across time (McGill and Van Ryzin, 1999).⁸ The pricing department also gathers and interprets competitor fares and initiates/responds to industry-level changes, e.g., implementing a fuel surcharge. These fare choices are given to the RM department, which is responsible for demand analysis, developing and updating flight-level forecasts, and merging all departments' inputs into the pricing heuristic.

While our study is limited to a single airline, we verify that this organizational structure is used widely by firms in several important industries. In Tables C.10 and C.11 in Appendix C, we document excerpts of job postings and professional network profiles that show all major airlines—including legacy carriers, low-cost carriers, and start-up airlines—maintain separate pricing and RM departments. We also find that the observed organizational structure can be

⁷Advance purchase (AP) fares are common at 7, 14, and 21 days before departure.

⁸The pricing department decides fares that cover different classes of service, connecting options, blackout dates, etc. Each fare has dozens of characteristics that can be adjusted.

found in car rentals, hotels, cruises, trains, and even at the rideshare service Uber. Therefore, we believe our insights likely apply broadly to firms that solve complex pricing problems.

2.1 Pricing Heuristic Details and the Effects of Input Decisions

All department decisions—the schedule/capacity constraint set by the network planning department, the fare menu decisions of the pricing department, and the demand analysis and flight-level forecasts made by the RM department—are inputs to the pricing heuristic. A novel feature of our study is that we observe the heuristic used by the firm. This allows us to simulate market outcomes based on observed practices and permits us to separate the effects of individual department decisions in counterfactuals. We describe the heuristic’s basic properties here. We provide psuedo-code, a simple example, and additional details in Appendix A.

The airline uses a heuristic called Expected Marginal Seat Revenue-b, or EMSRb (Belobaba, 1987).⁹ EMSRb differs from dynamic pricing models in several important ways, including that it considers a sequence of static problems. It does not choose a price, rather, it allocates how many seats it is willing to sell at each fare (see Dana (1999) for related theoretical work). The lowest-available fare (LAF), or the price consumers readily see when shopping for flights, is the least expensive fare to which the heuristic allocates inventory. Throughout, we use “price” to refer to the lowest-available fare, and “fares” to refer to the pricing department’s input to the heuristic. The heuristic sets booking limits to segment demand. For example, if demand at higher prices is expected to be high, it will restrict the inventory it allocates to less expensive fares. Code revisions confirm the heuristic has been used at the firm for over 25 years.

To better understand the heuristic, imagine that there are two types of customers, high and low willingness to pay (WTP) customers. Low WTP customers are willing to pay $p_L < p_H$, and high WTP customers are willing to pay p_H . The heuristic assumes that all low WTP customers will arrive first, or more generally, that customers will arrive in increasing order of willingness to pay. It segments demand by calculating a protection level (x) that reserves capacity for high WTP customers. With a capacity C , the remaining $C - x$ units are offered to

⁹The heuristic was proposed by Peter Belobaba in his PhD thesis. There are multiple forms of EMSR. EMSRa differs from EMSRb in how remaining inventory is aggregated. We verify the version used by the airline by inspecting its code.

low WTP customers. What determines this threshold? The heuristic uses Littlewood's Rule, $p_H \cdot (1 - \Pr(Q_H \leq x)) = p_L$, where Q_H is the demand from the high WTP segment. This expression can be solved for x .¹⁰ This sets the opportunity cost of saving a seat for high WTP customers equal to the value of selling it today at p_L . As part of the optimization routine, the opportunity cost (OC) of selling a seat is computed. This is defined as the difference in expected future revenues (V) if the firm had one fewer seat to sell, i.e., $OC = V(C) - V(C - 1)$.

In practice, EMSRb is implemented in a two-stage process. First, aggregate demand is calculated. This is the sum of a flight's forecasted demand remaining over time, evaluated at the pricing department's fare choices. Second, it then recursively uses Littlewood's rule to set protection levels for each fare (the xs).¹¹ Because Littlewood's Rule requires two fares, EMSRb collapses the inverse demand curve above a given fare into a single statistic as it allocates capacity (see Appendix A for an illustrative example and mathematical expression). This simplification makes it a heuristic—its solution does not correspond to solving an economic problem. However, its assumptions allow it to re-optimize remaining inventory easily, whereas solving dynamic programs at scale is very difficult due to the curse of dimensionality.

The heuristic also makes a number of additional consequential simplifications. For example, it does not internalize the existence of any substitutes. Observing identical prices for flights offered by the airline within a day or across competitors is made possible by the pricing department's actions, but it is not enforced by the heuristic.¹² An important limitation of our study is that although we model fare decisions, we do not study potential competitor responses to these decisions. While offering simple fare structures may be useful for competitive reasons (Cyert, Kumar and Williams, 1995), our analysis focuses on how it can be used for market segmentation.

Decomposing the problem across departments can create challenges because all department inputs can affect how the heuristic allocates remaining inventory. For example, suppose that

¹⁰The idea was developed by BOAC airline employee Ken Littlewood.

¹¹The heuristic does not consider ancillary revenue, including baggage fees, upgrade charges, etc., when it makes its decisions. Fares are not personalized.

¹²In the case of substitute flights at the airline, fare menus vary by departure date but not across flights within the same day. For routes with exactly two daily frequencies, we find that both flights have identical prices 60% of the time. In the case of substitute flights at other airlines, the pricing department may choose a similar fare menu to its competitors. Betancourt et al. (2023) document similar price matching in markets with competition.

the pricing department wants to run a sale (or match a competitor) by adding a low fare to the menu. This fare decision is fed through the RM department's demand model to create forecasts. If protection levels are such that the lowest fare receives positive allocation, then seats will be offered at the sale fare. However, if the forecasts are such that the heuristic protects a significant amount of inventory at higher fares, it may not allocate any inventory to the sale fare. That is, the RM department's demand input (or network planning input) can offset the pricing department's intentions. Consequently, unilateral department actions may lead to limited change (Milgrom and Roberts, 1990, 1995).

3 Data and Summary Analysis

We use comprehensive data from a large international airline based in the United States. We first describe the routes we study. We then introduce and summarize the data. We provide descriptive evidence on department decisions in Section 4.

3.1 Route Selection

We select a subset of routes to study because of data size constraints. We apply the selection criteria below to the publicly available DB1B data provided by the Bureau of Transportation Statistics.¹³ Using data from the first three quarters of 2018, we filter routes (origin-destination pairs) based on the following criteria:

- i) Combine nearby airports to create "city codes;"
- ii) Remove routes where over 10% of passengers fly on carriers that do not make their tickets available on third-party websites;
- iii) Retain routes where at least 25% of passengers fly on the airline we study;
- iv) Retain routes where at least 750 passengers fly quarterly;
- v) Remove routes where fewer than 500 passengers fly nonstop quarterly;

¹³We scale passenger volume by 10× because the DB1B is a 10% sample of domestic tickets sold. The DB1B does not include key ticket details, including the date of purchase, the date(s) traveled, and the flight numbers involved. Therefore, we use the DB1B solely for route selection.

- vi) Retain routes where the airline we study provides daily nonstop service.

Selection criterion (i) ensures that our market definition covers relevant airport substitution. Our groupings follow existing work, e.g., Berry (1992).¹⁴ Criterion (ii) removes routes where competitor information may not be available to the airline¹⁵, (iii) ensures that our data contains meaningful amount of traffic on our airline, (iv) eliminates small routes, and (v) ensures that markets have meaningful nonstop traffic.

We perform these operations for all three quarters separately and take the union of routes. Given the resulting set, we sort routes based on the fraction of passengers flying nonstop (decreasing). We select the first 470 routes from this list. Our selection criteria result in a diverse set of routes in terms of competition, capacities, flight frequencies, and traffic flows. The sample contains large routes between major cities as well as routes from metropolitan areas to small cities. For 60% of routes in the sample, the airline faces no direct nonstop competition. For the remaining 40% of routes in the sample, the number of nonstop competitors ranges from one to seven. We obtained data over two years and created a sample of flights that departed between August 1, 2018 and August 31, 2019.¹⁶

In Appendix B, we present more detailed summaries of the routes studied and compare route characteristics in our sample to all U.S. domestic travel.

3.2 Data Overview

We combine (1) bookings, (2) inventory, (3) search, (4) fares, and (5) forecasting data. We describe each data set, identifying key variables used. In Appendix C.2, we provide a synthesized observation for each table.

(1) Bookings data: We observe all economy tickets purchased, regardless of booking channel, e.g., the airline’s website, travel agency, etc. The data are analogous to what a consumer observes after booking a flight, e.g., the routing, flight numbers, departure date(s) and time(s), fare paid, number of passengers, and the booking channel.

¹⁴The groupings are: (HOU, IAH); (DFW, DAL); (BWI, DCA, IAD); (MDW, ORD); (EWR, JFK, LGA); (LAX, LGB, ONT, SNA, BUR, SBA); (SFO, OAK, SJC).

¹⁵This removes Allegiant and Southwest. We do not study strategic interactions—see Betancourt et al. (2023).

¹⁶Data transfer began in 2019, before the release of each quarter of the 2019 DB1B.

(2) *Inventory data*: The inventory data contain the daily decisions made by the pricing heuristic. For every flight, each day before departure, the data record the number of seats the airline is willing to sell at each price level. Also included in the data set are the departure and arrival times, the actual capacity, the authorized capacity in case overselling is allowed, and the heuristic’s calculated opportunity cost of capacity, which is its approximation of the difference in expected revenues if the flight had one fewer seat remaining. In addition, we observe the pricing heuristic’s code.

(3) *Search data*: We observe all “clicks” on the airline’s website for two years. The search data contain over one billion data points which track how consumers engage with the website. We extract all entries related to the action of submitting a search query, which we use to measure market sizes (see Appendix C.3 for our cleaning procedure).

(4) *Fare data*: The fare data contain the pricing department’s decisions. Fares vary by route and departure date, but not across flights within a departure date. Typically, the same fare menu is shared by multiple departure dates. A fare includes both a price and specific ticket conditions, such as advance purchase requirements, flexibility restrictions, eligibility for refunds (including fully refundable fares), and limitations on services (often referred to as “basic” fares). Each fare is categorized into one of approximately a dozen “fare classes,” which are used by the heuristic. Although pricing analysts may adjust individual fares over time, the median number of changes to a given fare is one in two years of data. We focus on one-way fares as round-trip discounts are rare in the routes studied. We provide an example fare menu for a European airline in Appendix C.2, Table C.16.

(5) *Forecasting data*: The RM department forecasts short-run demand using a single-product demand model. Forecasts are maintained from the time a flight is initially scheduled until the departure date. We observe the econometric demand model, denoted $Q(p; \theta)$, used to create these forecasts as well as the parameter estimates ($\hat{\theta}$). All domestic routes rely on one of six demand specifications (sets of parameters), which allow demand to vary by day before departure, day of the week, and consumer type.¹⁷ The RM department maintains separate demand models

¹⁷We observe the demand model in presentations and the parameter estimates in a database. One set of demand parameters may be applied to dissimilar routes, such as a small, single-carrier route with a single daily flight and the largest route in terms of daily frequencies and nonstop competition.

for “business” and “leisure” travelers. Plugging in a route/consumer type’s associated $\hat{\theta}$ yields $Q(p; \hat{\theta})$, which we refer to as the “baseline demand model.”

The baseline demand model is adjusted by analysts in seven-day intervals (these are the noticeable spikes in Figure II). Analysts look at recent flight performance to make these adjustments. These adjustments ($\hat{\theta}^{\text{adj.}}$) are critical because they are the only way to include seasonality and departure date effects, which are not considered in the baseline demand model. We refer to the demand model, inclusive of analysts adjustments, as the “demand forecasts.” The demand forecasts are still demand curves, i.e., $Q(p; \hat{\theta}^{\text{adj.}})$. These forecasts are aggregated across consumer types and evaluated at the pricing department’s fare menus to form an input to the heuristic.¹⁸

3.3 Summary Analysis

Table I provides a basic summary of the 300,000 flights in our sample. We focus on the last 120 days before departure due to the overwhelming sparsity of search and sales observations earlier in the booking horizon. Although consumers commonly have access to several fares at any given point in time, we define the lowest-available fare (LAF), or “price,” to be the lowest, non-basic economy fare available for purchase. This matches the definition used by the heuristic. Moreover, the vast majority of consumers purchase the LAF. We find that 5.8% of consumers purchase basic fares, and 4.8% of consumers purchase more expensive fares.¹⁹ Because the fraction of consumers who do not purchase the LAF is relatively small, we simplify our analysis by assuming that all bookings occur at the LAF in our empirical analysis.

Average one-way prices in our sample are \$198, with large dispersion across routes and over time. We plot the frequency of price changes and average prices over time in Figure II. Typically, prices for a particular flight adjust nine times. Many fare adjustments occur at specified times, such as after expiration of AP opportunities (see the spikes Figure II-(a)). Over 60% of

¹⁸The demand models are aggregated based on the probability that a given ticket is purchased by a “leisure” or “business” traveler. The probability varies by day before departure and is fitted using historical data. In Section 6, we refer to this as the “passenger assignment algorithm.”

¹⁹Consumers with the highest statuses are most likely to buy tickets at fares above the LAF. This finding complements Orhun, Guo and Hagemann (2022), who show that loyal consumers tend to fly longer itineraries than necessary in order to obtain status at an airline whose loyalty program is mileage-based. We also note that special fares, such as corporate or government discounts, are rare in the routes studied.

Table I: Summary Statistics

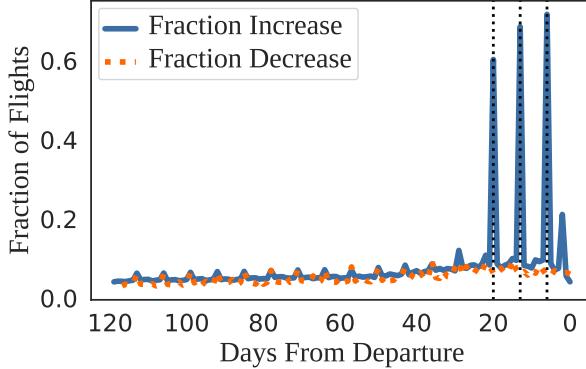

Variable	Mean	Std. Dev.	Median	5th pctile	95th pctile
Prices					
One-Way Price (\$)	197.8	127.2	162.2	87.0	404.1
Num. Price Changes	9.3	4.1	9.0	3.0	17.0
Price Change (\$), Cond. on Inc.	49.8	71.3	31.2	2.2	161.2
Price Change (\$), Cond. on Dec.	-52.0	73.3	-32.2	-168.8	-4.3
Booking					
Booking Rate-OD	0.2	0.7	0.0	0.0	1.0
Booking Rate-All	0.6	1.4	0.0	0.0	3.0
Ending LF (%)	81.8	21.9	90.0	35.8	102.0
Searches					
Search Rate	1.8	4.8	0.0	0.0	9.0

Note: One-way price measures the lowest-available economy fare. The number of price changes is calculated for each flight from 120 days before departure to the departure date. The price change statistics separate price increases from decreases and are reported in levels. The booking rate (OD) is computed at the flight, day before departure level and measures non-award, nonstop economy bookings. OD stands for origin-destination (or route). The booking rate (all) is computed at the flight, day before departure level and measures all economy bookings that involve the flight. Ending load factor is calculated for each flight and measures the percentage of economy seats occupied at departure. The search rate measures the number of passengers involved in searches at the OD, departure date, day before departure level using the clickstream data.

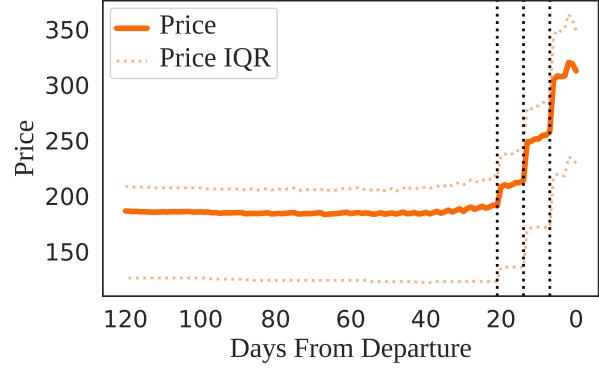

all price adjustments occur outside these time windows. In Figure II-(b), we plot average prices over time. Prices increase by over 70% in 120 days. Prices increase even for flights with low realized demand due to AP discounts expiring.

Figure II: Price Time Series

(a) Fraction of Price Changes

(b) Prices

Note: Panel (a) measures the fraction of flights that experience a positive/negative change in the lowest-available fare across consecutive days, by day before departure. Panel (b) shows the average price by day before departure. Also included is the IQR. Vertical dotted lines correspond to common advance purchase requirements.

The booking rate (quantity per flight-day) is low, and the percentage of zero sales is 89%. Importantly, the highest booking rates occur when prices are the highest, within the last 7 days

before departure. The average load factor (percentage of seats occupied) at departure is 82%. Although over 5% of flights eventually oversell, we abstract from this possibility because we do not observe denied boarding/no show information. We use the flight's authorized capacity in our analysis because that is the capacity used by the heuristic when it allocates remaining inventory. The median number of seats the RM department is willing to oversell in our sample is one.

3.4 Motivating Evidence on Demand

We provide new descriptive evidence to motivate many of our modeling assumptions. The bookings data suggest that unit demand is a reasonable assumption. The average number of passengers per booking is 1.3, and the median is 1.

We do not endogenize capacity choice, as only 2% of flights ever experience a change in capacity. Most changes occur more than 100 days before the departure date. 30% occur within 48 hours of departure (due to operational issues).

We adopt a two-type consumer model as is common in this literature.²⁰ As mentioned in Section 3.2, the RM department also uses a demand model with two consumer types.

We assume a static discrete choice model based on search patterns that we document.²¹ We “daisychain” the clickstream data by linking search activity across time using cookies (see Appendix C.3) and establish the following facts:

- i) 82% of consumers search a single departure date;²²
- ii) 90% of consumers complete all their search activity in a single day;
- iii) Among the 10% of consumers that search the same departure date over time; only 20% ever observe a lower fare for at least one flight in later searches;²³

²⁰For examples, see Berry, Carnall and Spiller (2006), Berry and Jia (2010), Lazarev (2013), Aryal, Murry and Williams (2022), and Williams (2022).

²¹All the cited literature in Footnote 20 assume short-lived buyers with the exception of Lazarev (2013), who assumes buyers know their future preferences, but are uncertain if they can fly, and that prices are deterministic.

²²Among the remaining 18%, the average time lag between these searches is 45 days, suggesting that consumers may be searching for different trips entirely.

²³Our estimates of consumer waiting are lower than estimates by Li, Granados and Netessine (2014), which are model-derived without access to search data.

- iv) 62% of consumers would have received a lower price if they shopped a week earlier; 8% would have benefited from delaying their purchasing decision.

We note that while many of our assumptions are also made in the RM department’s demand model (short-lived buyers, no substitution across departure dates and days before departure), these assumptions can affect estimated demand elasticities. In particular, Hendel and Nevo (2006) show in the retailing context without capacity constraints that assuming short-lived buyers when in fact consumers are forward-looking can lead to overstating consumer price sensitivity. That is, it is possible that demand may be more inelastic than our estimates suggest. Moreover, the extent to which consumers are flexible across departure dates and routes creates a product variety benefit that the pricing heuristic does not exploit.

4 Pricing Biases in Airline Markets

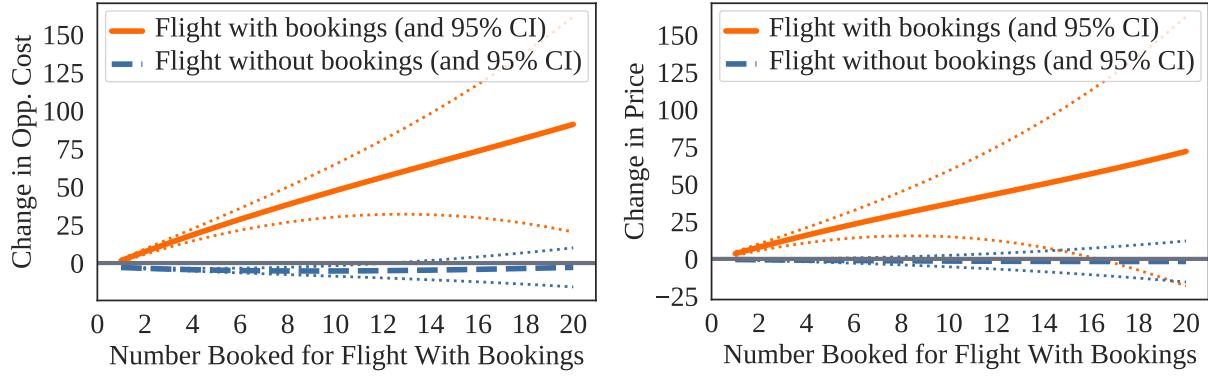

Using the firm’s data and internal models, we provide examples of pricing biases that affect all flights, regardless of market structure.

4.1 Heuristic Bias

The pricing heuristic used by the firm (see Section 2) greatly reduces computational burden because it avoids solving a dynamic program. However, this also makes the heuristic dynamically inconsistent, as it does not internalize that it will revisit its decisions every day. Another consequence of its design is that it does not account for cross-price elasticities of any kind, including across cabins within a flight, other flight options, and competitors. All flights, regardless of market structure, flight frequency, etc., are priced using the same single-product heuristic.

The heuristic does not even indirectly react to demand realizations of substitute flights. This precludes direct responses to competitors. We provide evidence of this non-response in Figure III. In Figure III-(a), we plot the average change in opportunity costs, as reported by the heuristic, for the flights that receive bookings and for the flights that do not receive bookings (the substitute option) using a polynomial regression (of degree four). Panel (b) shows the cor-

Figure III: Opportunity Cost and Price Response to Bookings with Multiple Flights
 (a) Opportunity Costs (b) Prices

Note: In panel (a), the orange line denotes the estimated conditional mean of the impact of bookings on the substitute flight on that flight's opportunity cost. The blue line denotes the conditional mean of the impact of bookings on the substitute flight on the focal flight's opportunity cost (flight without bookings). Also included are the 95% confidence intervals. The conditional mean is computed via polynomial regression of degree four. Panel (b) depicts the same analysis as panel (a), but with price as the outcome variable in place of opportunity cost.

responding price change.²⁴ The figure confirms opportunity costs and prices for the substitute flight are unaffected by bookings on the focal flight.

4.2 The Presence of Pricing Frictions

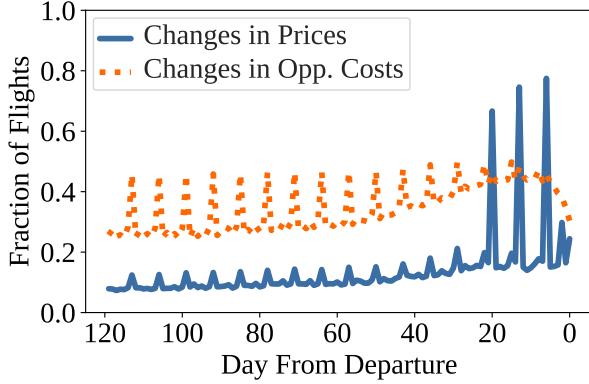

The use of discrete fare menus creates pricing frictions, which we directly measure using the firm's data. In Figure IV-(a), we plot the fraction of flights that experience changes in price or opportunity costs (OCs) as reported by the heuristic over time. Opportunity costs (the dotted orange line) change much more frequently than the prices consumers face (the solid blue line). The noticeable 7-day spikes in the figure reflect the fact that the RM department implements analyst adjustments in fixed, 7-day intervals before departure. Analyst adjustments lead to a larger fraction of flights experiencing a change in OCs and prices at those times.

In Figure IV-(b), we plot the fitted values of a logistic regression with a flexible polynomial expansion of degree four of the change in OCs on an indicator function of the price changing. We find that changes in OCs exceeding \$100 only lead to a change in the price with a 20% probability.

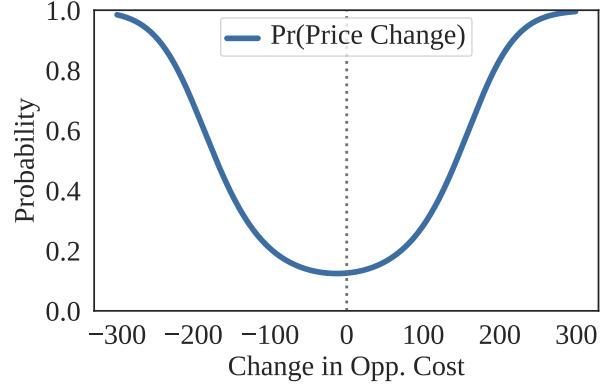

²⁴For this exercise, we select observations based on the following criteria: (i) the firm offers two flights a day, (ii) we include periods where demand is not being reforecasted (the observed spikes in Figure IV), (iii) one flight receives bookings and the other flight does not within a day, and (iv) the bookings do not cause a sellout.

Figure IV: Price Adjustments in Response to Opportunity Cost Changes

(a) Price vs. Opportunity Cost Changes

(b) Probability of Price Change

Note: Panel (a) shows the fraction of flights that experience changes in price/opportunity cost by days before departure. Panel (b) shows the probability of a price change (0–1), conditional on the magnitude of the opportunity cost (OC) change. The probability is calculated as the fitted values of a logistic regression of a polynomial expansion of degree four of the change in OCs on an indicator function of the price changing.

4.3 Allocating Inventory to Fares that do not Exist

All department decisions affect the heuristic's choices, and we show that the process of combining inputs is susceptible to "miscoordination." More specifically, we observe a misalignment between the fares used by the heuristic and the fare menus used for purchasing and ticketing. Such a situation can occur if the RM department has not fully integrated all the changes introduced by the pricing department into their fare menus.

To better understand this form of miscoordination, we provide an illustrative example. Imagine that the pricing department raises the lowest fare on the menu from \$100 to \$150, but this change is not implemented by the RM department, which manages inputs to the heuristic. Consequently, the heuristic optimizes the remaining inventory based on the original \$100 fare. It may choose to allocate only a single seat at \$100, given an optimistic forecast. However, when customers check the airline's website or other booking platforms, they will encounter the \$150 fare. A single seat will be available for purchase at that price. If the heuristic instead used the \$150 fare for inventory allocation, more than one seat might have been made available at that price.

We find that this form of miscoordination affects 11.7% of inventory allocations. It may arise because combining high-dimensional, frequently updated inputs across multiple IT systems, which interface both internally and externally, is a difficult process. Although we do

not directly study this form of miscoordination in our counterfactuals, we do simulate market outcomes under alternative fare menus, which implicitly removes this bias.

4.4 Fares on the Inelastic Side of Demand Curves

Another form of miscoordination that we observe is that the pricing department often files fares that are too low according to RM department’s estimated demand model. Although this would be inconsequential if the pricing heuristic solved an economic model—it would never offer a fare on the inelastic side of demand—in practice, the heuristic may not prevent “inelastic prices” from being offered to consumers.²⁵ When capacity is not sufficiently constrained, the heuristic may not protect enough seats at higher fares so that inventory is allocated to fares on the inelastic side of the RM department’s demand model. This can occur even if the more expensive, revenue maximizing fare is in the fare menu.

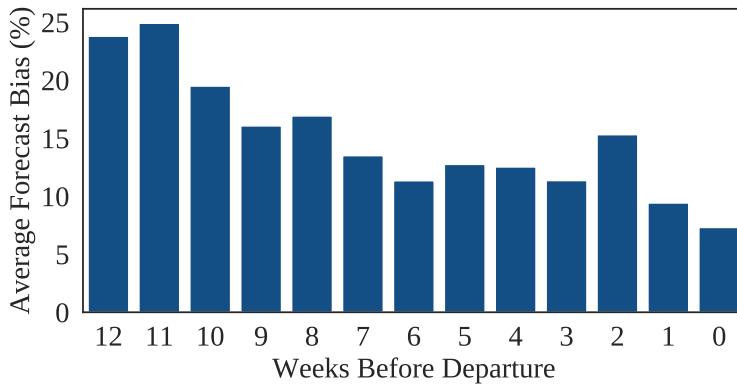

To quantify this form of miscoordination, we use the RM department’s continuous and differentiable demand model, $Q(p; \hat{\theta})$, to calculate the elasticity of demand, $e(p; \hat{\theta})$. We plug in each route’s parameter values and the lowest fare filed by the pricing department. We find that if the heuristic allocated seats to these fares, consumer demand would be inelastic according to the RM department’s demand model in 98% of the sample. One compelling reason for the persistence of low fares on the menu is that the pricing department chooses fares without the use of internal demand estimates (email interview with a manager, December 22, 2022). However, if departments have alternative objectives and/or are uncertain about the demand parameters themselves, this could also explain the persistence of “inelastic prices.” We discuss this further in Section 6.

²⁵In a dynamic pricing model with a single firm, opportunity costs are positive values as they are defined by the difference in continuation values if the firm had one fewer seat to offer, i.e., $OC_t = V_t(C) - V_t(C - 1)$. As shown in Betancourt et al. (2023), the optimal price comes from maximizing $Q_t(p_t)(p_t - OC_t)$, which is solved via backward induction. Given a demand function that is continuously differentiable such that $Q_t(p_t)(p_t - OC_t)$ attains a max where $p^* \neq 0$ or ∞ , then it follows from the resulting markup formula that $e^D(p^*) \leq -1$.

4.5 Using Persistently Biased Forecasts

Finally, we find evidence that RM analysts adjust the underlying demand model in a persistent way—they inflate it, which leads to a systematic overprediction of demand as an input to the heuristic. We find that this is nearly always accommodated by scaling up all routes’ demand predictions simultaneously by a common factor.

Figure V: Forecast Bias by Week Before Departure

Note: Forecast bias is calculated by comparing expected demand to realized demand and normalizing by realized demand. We observe forecasts at the flight, day before departure, departure date, route, and price level. The mean forecast bias is computed by week before departure at the current LAF.

In Figure V, we plot the average forecast bias by week before departure. We calculate the forecast bias for a particular week before departure as

$$\text{Forecast Bias} := 100 \cdot \frac{\sum_{j,d,t} \text{EQ}_{j,d,t}(p_{j,d,t}) - \sum_{j,d,t} \text{Q}_{j,d,t}(p_{j,d,t})}{\sum_{j,d,t} \text{Q}_{j,d,t}(p_{j,d,t})},$$

which is the difference between forecasted (EQ) and realized (Q) demand, over realized demand (Q), at observed prices. We sum over all flights (j), departure dates (d), and days before departure (t), for a given week. We find that the average forecast bias ranges between 25% and 7% by week before departure, and that the bias shrinks towards departure. 93% of flights are initially overforecasted. Interestingly, we find that routes with nonstop competitors feature larger forecasting bias (by 8.1%) compared to single-carrier routes on average. This may be due to the increased complexities of using a single-product demand model in markets with competition.

While observing persistently biased forecasts is consistent with several behavioral biases, including overconfidence/overoptimism (Camerer and Lovallo, 1999; Huffman, Raymond and

Shvets, 2022) and over- and under-reaction to information (Bordalo et al., 2020), research in operations has shown that the pricing heuristic used by the firm may result in “underpricing” due to the heuristic’s assumptions (Wollmer, 1992; Brumelle and McGill, 1993; Cooper, Homem-de Mello and Kleywegt, 2006). Upward forecasting bias is consistent with the RM department using a workaround, or kludge, to address heuristic bias. Conversations with a manager corroborate our interpretation that biased forecasts are meant to address heuristic bias (email interview, July 16, 2021).

We find that the upward forecasting bias, along with demand shock realizations, decreases the fraction of flights subject to pricing on the inelastic side of demand according to internal demand model estimates from 98% to 38%. Although routes with nonstop competition feature larger forecasting biases, they retain more frequent inelastic demand (by 9.9%).

5 Empirical Model of Air Travel Demand

Our goal is to study the impacts of delegated decision-making and the use of heuristics on market outcomes. While we directly observe how prices are set, we do not directly observe consumer preferences. Moreover, the evidence presented in Section 4 suggests that the internal model of demand may not reflect true underlying preferences that generate demand. Therefore, we estimate demand. In this section, we present our demand model, estimation procedure, and parameter estimates. We use the model estimates in counterfactuals.

We maintain a granular market definition, defining a market to be an origin-destination (r), departure date (d), and day before departure (t) tuple. We suppress the r subscript. All parameters are route-specific. The booking horizon for each flight j leaving on date d is $t \in \{0, \dots, T\}$. The first period of sale is $t = 0$, and the flight departs at $t = T$. In each market t , arriving consumers choose flights from the choice set $J_{t,d}$ that maximize their individual utilities, or select the outside option, $j = 0$. The choice set may change due to a sellout. Our demand model captures all nonstop bookings.

5.1 Utility Specification

Like the firm, we assume that arriving consumers are one of two types, which we also label as leisure (L) travelers and business (B) travelers, though these types do not need to correspond to the firm's types or the reason for travel. An individual consumer is denoted by i and her consumer type is denoted by $\ell(i) \in \{B, L\}$. The probability that an arriving consumer is a business traveler is equal to γ_t . We incorporate two assumptions to simplify our analysis. First, we assume that consumers do not choose flights based on remaining capacity, $C_{j,t,d}$. This allows us to avoid modeling infrequent events where a consumer may otherwise choose a less preferred option because there is a higher probability of securing a seat. Second, we incorporate random rationing if demand exceeds remaining capacity.

We assume that indirect utilities are linear in product characteristics and given by

$$u_{i,j,t,d} = \begin{cases} X_{j,t,d}\beta - p_{j,t,d}\alpha_{\ell(i)} + \xi_{j,t,d} + \varepsilon_{i,j,t,d}, & j \in J_{t,d} \\ \varepsilon_{i,0,t,d}, & j = 0 \end{cases},$$

where $X_{j,t,d}$ denotes product characteristics other than price $p_{j,t,d}$, and preferences are denoted by $(\beta, \alpha_\ell)_{\ell \in \{B, L\}}$. The choice set may vary over time due to sellouts. The term $\xi_{j,t,d}$ denotes an unobserved demand shock that is potentially correlated with price, and $\varepsilon_{i,j,t,d}$ is a random component of utility that is assumed to be distributed according to a type-1 extreme value distribution. Consumer i chooses flight j if and only if $u_{i,j,t,d} \geq u_{i,j',t,d}, \forall j' \in J_{t,d} \cup \{0\}$.

The distributional assumption on the idiosyncratic error term leads to analytical expressions for the individual choice probabilities (Berry, Carnall and Spiller, 2006). The probability that consumer i chooses flight j is equal to

$$s_{j,t,d}^i = \frac{\exp(X_{j,t,d}\beta - p_{j,t,d}\alpha_{\ell(i)} + \xi_{j,t,d})}{1 + \sum_{k \in J(t,d)} \exp(X_{k,t,d}\beta - p_{k,t,d}\alpha_{\ell(i)} + \xi_{k,t,d})}.$$

We define $s_{j,t,d}^L$ to be the conditional choice probability for a leisure consumer, and $s_{j,t,d}^B$ for a business consumer. Integrating over consumer types, we can write the choice probability for flight j as $s_{j,t,d} = \gamma_t s_{j,t,d}^B + (1 - \gamma_t) s_{j,t,d}^L$.

5.2 Arrival Processes and Integer-Valued Demand

Whereas the empirical literature commonly assumes market sizes, we model consumer arrivals and estimate arrival rates based on aggregate search counts. This allows us to measure aggregate demand uncertainty. We assume that both consumer types arrive according to time-varying Poisson distributions such that: (i) arrivals are distributed Poisson with rate $\lambda_{t,d}$, (ii) arrivals are independent of price (see Appendix C.4 for supporting evidence) and $\xi_{j,t,d}$, and (iii) consumers solve the above utility maximization problems. With these assumptions, conditional on prices and product characteristics, demand for flight j is equal to

$$\tilde{q}_{j,t,d} \sim \text{Poisson}\left(\lambda_{t,d} \cdot s_{j,t,d}\right).$$

Realized demand may be censored, i.e., $q_{j,t,d} = \min\left\{\tilde{q}_{j,t,d}, C_{j,t,d}\right\}$.

5.3 Empirical Specification

The richness of the data allows us to capture route- and time-varying demand in a flexible way. All parameters are estimated at the route level. We assume that consumer utility is given by (using the r subscript for this subsection only to stress flexibility)

$$u_{i,j,t,d,r} = \beta_{0,r} - \alpha_{\ell(i),r} p_{j,t,d,r} + \text{FE}_r(\text{Time of Day } j) + \text{FE}_r(\text{Week } d) + \text{FE}_r(\text{DoW } d) + \xi_{j,t,d,r} + \varepsilon_{i,j,t,d,r},$$

where "FE" denotes fixed effects for the variable in parentheses. We allow price to be correlated with ξ via a pricing equation that we formalize below.

We parameterize the probability that an arriving consumer is a business traveler as

$$\gamma_{t,r} = \frac{\exp(f_r(t))}{1 + \exp(f_r(t))},$$

where $f_r(t)$ is an orthogonal polynomial basis of degree five with respect to days before departure. This specification allows for non-monotonocities while producing values bounded between zero and one. We specify the arrival processes using a multiplicative relationship between day

before departure and departure date using fixed effects, i.e., $\lambda_{t,d,r} = \exp(\lambda_{t,r} + \lambda_{d,r})$. We choose this specification because consumer arrivals are observed at the (t, d, r) level of granularity, searches tend to increase over time or evolve discontinuously ($\lambda_{t,r}$), and we observe strong departure-date effects ($\lambda_{d,r}$).

Our method does not require that we observe all searches. Because we observe all bookings, under an additional assumption, and using properties of the Poisson distribution, we can scale up our estimated arrival rates to account for unobserved searches. More precisely, we assign $A_{t,d,r} \sim \text{Poisson}(\lambda_{t,d,r}/\zeta_{t,r})$, where $\zeta_{t,r}$ denotes the fraction of bookings for route r at time t that are made directly with the airline. Implicitly, we assume that the distribution of preferences for consumers that shop via other channels is identical to the observed channel. For example, if observed searches account for 20% of bookings, we can scale up estimated arrival rates by 5× using properties of the Poisson distribution. We conduct several robustness checks to assess the sensitivity of our estimates to our choice in scaling factors (see Section 5.6).

5.4 Estimation Procedure

We estimate demand using a hybrid-Gibbs sampler. This splits up estimation across parameters, as simultaneously drawing from the joint distribution of a large parameter space is computationally challenging. Our approach allows us to estimate hundreds of demand parameters per route, rationalize the large number of zero-sale observations, and maintain a Bayesian IV correlation structure between price and the aggregate demand shock ξ . Our approach builds on the estimation procedure developed by Jiang, Manchanda and Rossi (2009) by incorporating arrival processes, discrete random coefficients, and censored demand. Hortaçsu et al. (2023) conduct Monte Carlo exercises and present a generalized version of this model that can also accommodate continuous random coefficients.

We present the estimation algorithm below and then describe each step. At each step, we sequentially draw from the marginal posterior distribution groups of parameters, conditional on other parameter draws. We list the prior distribution choices in Appendix D.2.

Algorithm 1 Hybrid Gibbs Sampler

```

1: for  $c = 1$  to  $C$  do
2:   Update arrivals  $\lambda$                                      (Metropolis-Hastings)
3:   Update choice probabilities  $s(\cdot)$                       (Metropolis-Hastings)
4:   Update price coefficients  $\alpha$                            (Metropolis-Hastings)
5:   Update consumer distribution  $\gamma$                          (Metropolis-Hastings)

8:   Update price endogeneity parameters  $\Sigma$                 (Gibbs)
9: end for

```

Updating arrival parameters. We start the sampling procedure by drawing from the posterior distribution of arrival parameters, $\lambda_{t,d} = \exp(\lambda_t + \lambda_d)$. The posterior is derived by defining the joint likelihood of arrivals for each consumer type and quantities sold, conditional on choice probabilities and capacity constraints. The likelihood of arriving consumers is $A_{t,d} \sim \text{Poisson}(\lambda_{t,d}/\zeta_t)$, where ζ is calibrated from the data.

Updating choice probabilities. Zero-sale observations are problematic because existing estimation approaches require strictly positive empirical choice probabilities, and dropping these observations creates a selection bias in the estimates (Berry, Linton and Pakes, 2004). Our approach accommodates zero-sale observations by treating product market shares as unobserved (due to sampling error). We use data augmentation to treat market shares as latent parameters that we estimate. Conditional on all other parameters, choice probabilities are an invertible function of the demand shocks, ξ . We leverage the stochastic nature of ξ , which we explicitly parameterize. The distribution of unobserved ξ is the source of variation for constructing a conditional likelihood for choice probabilities and the pricing equation:

$$\left. \begin{array}{l} \xi_{j,t,d} = f^{-1}(s_{j,t,d}) \\ v_{j,t,d} = p_{j,t,d} - Z'_{j,t,d}\eta \end{array} \right\} \Big| t, X, Z \sim \mathcal{N}_{\text{iid}}(0, \Sigma_t)$$

such that $\Sigma_t = \begin{pmatrix} \sigma_{t,11}^2 & \rho_t \\ \rho_t & \sigma_{t,22}^2 \end{pmatrix}$.

Conditional on the shock v in the pricing equation, the distribution of ξ , $f_{\xi_{j,t,d}}(\cdot)$, is

$$\xi \mid v, \sim \mathcal{N} \left(\frac{\rho_t v}{\sigma_{t,11}^2}, \sigma_{t,22}^2 - \frac{\rho_t^2}{\sigma_{t,11}^2} \right).$$

Choice probabilities are given by the transformation $f_{s_{j,t,d}}(x) = f_{\xi_{j,t,d}}(f^{-1}(x)) \cdot |\mathcal{J}_{\xi_{j,t,d} \rightarrow s_{j,t,d}}|^{-1}$, where $\mathcal{J}_{\xi_{j,t,d} \rightarrow s_{j,t,d}}$ is the Jacobian matrix of choice probabilities with respect to ξ . To produce the full joint conditional likelihood, we also include the mass function for sales, which is the product of choice probabilities and arrivals.

Updating price coefficients, α_B, α_L . We construct the conditional likelihood for $\alpha = (\alpha_B, \alpha_L)$ in a similar manner to the choice probabilities. For any candidate vector of price sensitivity coefficients, we invert the demand system which allows us to derive the likelihood. Conditional on λ, s, η, β , and Σ , we compute the distribution of ξ and determine the likelihood of a particular draw of α . We impose a log-Normal prior on α , and impose $\alpha_B < \alpha_L$ to avoid label-switching.

Updating the distribution of consumer types, γ . We allow for the mix of consumer types to change over the booking horizon t . We define γ from a sieve estimator of the booking horizon t , and we sample the sieve coefficients, ψ , according to $\gamma_t = \text{Logit}(G(t)' \psi)$, where $G(t)$ is a vector of Bernstein polynomials. The logistic functional form ensures that the image of γ is in the interval $(0, 1)$.

Updating remaining preferences, β . We conduct a Bayesian regression step after adjusting for price endogeneity. We define $\delta_{j,t,d} = X_{j,t,d}\beta + \xi_{j,t,d}$, which is evaluated at ξ as computed in the previous step. We normalize each component of δ by subtracting the expected value of ξ and dividing by its standard deviation, which enables using a normal conjugate prior.

Updating pricing equation, η . We use a linear pricing equation of the form

$$p_{j,t,d} = Z_{j,t,d}\eta + v_{j,t,d}.$$

Conditional on $s, \lambda, \gamma, \alpha$, and β, ξ is known. Therefore, we use the conditional distribution of v given ξ to perform another Bayesian linear regression in a similar manner to β . We describe our choice of instruments (Z) in the next subsection.

Updating the price endogeneity parameters, Σ . We flexibly model the joint distribution of ξ

and v through Σ_t . We pool observations to estimate the variance-covariance matrix by mapping t to an interval of time. More precisely, we divide the booking horizon into four equally sized 30-day blocks. We use k to denote a block. We draw the variance of this normal distribution with an Inverse-Wishart parameterization. Our prior for Σ_k is $IW(\nu, V)$. We define the vector $Y_k = (v, \xi)$ to be the collection of residual pairs conditional on block k , and $Y_k \sim \mathcal{N}(0, \Sigma_k)$. The posterior for the covariance matrix Σ_k is given by

$$\Sigma_k \sim IW(\nu + n_k, V + Y_k' Y_k),$$

where block k has n_k observations. This Gibbs step is repeated for each block k , and we sample directly from the conditional posteriors of Σ .

5.5 Identification and Instruments

Estimating models of aggregate demand uncertainty is challenging because it requires identifying shocks to arrivals separately from preferences. Typically, arrivals are either assumed or recovered from imposing supply restrictions. We take a different approach by using arrivals data to address this problem. By observing arrivals (and accounting for unobserved arrivals), we can identify preference parameters using the same variation commonly cited in the literature on estimating demand for differentiated products using market-level data. The flight-level characteristic parameters are identified from the variation of flights offered across markets, and we identify the price coefficients using instrumental variables ($Z_{j,t,d,r}$). These variables are included in the pricing equation but are excluded from the demand model. We construct several instruments and verify that our demand estimates are robust to the choice of instruments.

The first instrument we construct is a cost shifter—we use a cubic polynomial of the opportunity costs calculated by the pricing heuristic, which vary at the j, t, d, r -level. If opportunity costs were not orthogonal, then there must be persistence over time in the unobserved determinants of demand that occurs at the flight-departure date level. Second, we use AP indicators to account for the fact that prices may adjust even in situations where opportunity costs are not observed to change (see the spikes in the frequency of price changes at 21, 14, and 7 days

from departure in Figure IV). These instruments vary at the r, t -level. Finally, we consider a network congestion instrument, inspired by “Hausman instruments” or “Fan instruments,” that involves cost-related markets. This instrument is defined as the number of inbound (or out-bound) bookings to a route’s hub airport that can potentially impact the prices consumers face on a given route and varies at the t, d, r -level. Consider a flight from O to D , where D potentially provides service elsewhere. We calculate the number of passengers traveling from D to an alternative destination D' . We assume that demand on leg $D - D'$ is independent of demand on $O - D$. Thus, a positive shock to onward traffic, out of airport D , will create scarcity in both $O \rightarrow D \rightarrow D'$ and $D \rightarrow D'$. This can propagate to prices on $O \rightarrow D$ due to the shared capacity constraint, similar in spirit to shared costs across markets with differing demand.²⁶ RM analysts can capture network scarcity effects by scaling up or down multiple routes’ demand predictions via their adjustments, e.g., capturing a hub-level demand shock.

Note that our identification argument does not rely on “optimal pricing.” The pricing heuristic’s decisions depend on scarcity, and we use its calculated opportunity costs as instruments in a flexible way by also adding quadratic and cubic terms. Our instruments are relevant and highly correlated with price because our pricing equations essentially approximate the heuristic’s decisions. For example, suppose that the forecast for a flight is persistently biased upward, but a flight’s demand shocks tend to be low. Our approach rationalizes this scenario because large opportunity costs rationalize higher prices. Our estimates recover low ξ s which differ in a flexible way from the pricing equation unobservables. These correlations may even be negative; that is, prices may be *high* even though our demand estimates suggest that prices should be *low*. In Appendix D, we report (pseudo) first-stage R^2 s for each route, which vary between 60%–90% across routes.

²⁶For a route with origin O and destination D , where D is a hub, the total number of outbound bookings from the route’s hub airport is defined as $\sum_{i=1}^K Q_{D,D'}$, in which $Q_{D,D'}$ is the the total number of bookings in period t , across all flights, for all K routes where the origin is the original route’s destination. If the route’s origin is the hub, we calculate the total number of inward bound bookings as $\sum_{i=1}^K Q_{O',O}$, in which $Q_{O',O}$ is the total bookings from all K routes where the original routes origin is the destination.

5.6 Demand Estimates

We estimate demand for a large fraction of routes in our sample, however, we do not investigate all routes. We use two selection criteria. First, we remove routes with nonstop competition. Therefore, our empirical analysis investigates single-carrier, nonstop routes. Second, we randomly select 140 routes, or one-half, of the remaining routes. We do this for computational reasons.

Our estimation sample features lower passenger counts compared to the entire sample, especially as compared to routes with competition. However, the selected routes are not statistically significantly different in terms of the fraction of nonstop and non-connecting traffic from the single-carrier only routes that we do not investigate. Appendix B.1 presents additional comparisons between the estimation sample and the full sample. In total, we estimate 235,000 demand parameters in our baseline specification.

Table II: Demand Estimates Summary

Elasticity	e	-1.079	0.538	-0.970	-1.340	-0.722

Note: The table reports parameter estimates for the 140 routes in the estimation sample. Statistics are calculated over routes, i.e., first the posterior mean of every parameter is calculated for each route. Reported here are moments of the distribution of posterior means across routes.

We summarize our demand results given the large number of parameters estimated. A complete presentation of the demand results appears in Appendix D.1, which provides route-level

price coefficients, day-of-week preferences, average estimated probability of business, percentage of zero-sale observations, pseudo first-stage R^2 , average estimated arrivals, empirical and model predicted bookings, and flight-level elasticities. We present these same estimates aggregated over routes in Table II. We find that leisure consumers are on average five times more price sensitive (-1.568 versus -0.267) than business consumers. For the average route, 39% of arrivals are business travelers. The interquartile range (IQR) across routes is 26% – 46%. Consumers generally prefer Monday travel, and Saturday has the lowest demand. Preferences for Wednesday and Thursday are similar. In our estimation sample, there is consistently a high fraction of zero-sale observations. The average route has 91% zeros, with an IQR of 90%–94%. This is slightly higher (vs. 89%) than the overall sample due to the estimation routes having smaller traffic volume. In general, arrivals are low, at roughly 1.7 searches per day. Finally, we estimate average flight-level elasticities to be near unit elastic, at -1.1, with an IQR of -1.3 to -0.7. Observing near unit-elastic demand does not imply that capacity is not important. In our context, this could stem from the fact that prices are not set by a rational, unitary decision-maker.

Figure VI: Estimated Arrivals and Elasticities, Aggregated Across Routes
 (a) Arrivals (b) Own-Price Elasticity

Note: Panel (a) shows the fitted arrival rates for routes in the estimation sample. The mean, median and IQR are plotted for each day before departure and calculated across routes. Panel (b) shows own price-elasticities using posterior means. The mean, median and IQR are plotted for each day before departure and calculated across routes.

In Figure VI-(a), we plot arrival rates for the average route as well as the IQR across routes. Although levels of arrivals vary—the interquartile range spans more than a doubling of arrivals across routes—overall, search increases as the departure date approaches. This means that

the observed increase in booking rates is not entirely driven by late-arriving, price insensitive consumers. Instead, there is also more interest in travel. In Figure VI-(b), we plot the average flight-level price elasticities for the mean, median, and IQR over routes. We find that demand becomes significantly more price inelastic over time as the mix of consumers changes. The decline in elasticities close to the departure date does not reflect a decrease in willingness to pay, but rather very significant price increases (over 70%). We frequently estimate inelastic demand close to the departure date, which we also find using the firm’s internal demand model (see Section 4).

Our demand results are robust to several alternative specifications, which we report in Appendix D. First, we re-estimate demand for all the routes in our estimation sample using two alternative instrument specifications: solely using the opportunity cost instrument and, separately, solely using the onward connecting traffic instrument. Table D.34 and Table D.35 present a summary of these alternative demand estimates. Figure D.20 graphically compares price coefficients across specifications. We find quantitatively similar preference estimates and demand elasticities. Second, we conduct robustness to the scaling factors used in estimation. We scale arrivals up by an additional 50% and then re-estimate demand for all routes. This allows us to investigate how our demand estimates change with significantly larger arrival rates compared to our baseline estimates. Table D.36 contains a summary of the results, and Figure D.21 graphically compares price coefficients. We find quantitatively similar estimates: average demand elasticities only change by 0.05. Finally, we estimate demand using a single route (“Route 1”), which has similar demand to the overall average ($\text{elas} = -1.1$), using 14 alternative scaling adjustments. We scale arrivals between $2\times$ and $5\times$ (in increments of 0.5) for all days from departure, and we apply these scaling factors only to days from departure greater than 30, where consumers may primarily search via online travel agencies. We find similar demand elasticities across specifications (see Tables D.37-D.38).

6 Analysis of Department Pricing Input Decisions

6.1 Counterfactual Setup

With demand estimated, we turn to our model of supply. We use our demand estimates and the heuristic described in Section 2 to simulate counterfactual market outcomes based on a set of department input decisions.²⁷ The goal of our first counterfactuals is to evaluate if observed department inputs are consistent with revenue maximization of the firm. We do not consider alternative incentives, objectives, or information structures given that we do not observe managerial compensation or variation in organization structure. Prices depend on the fare menu decisions of the pricing department, the demand forecasts set by the RM department, and the capacity choice set by the network planning department. Our baseline analysis uses observed fare menus (excluding basic economy), capacity decisions, and RM forecasts that account for analyst adjustments. We then consider unilateral deviations in department input decisions from the baseline.

For each counterfactual, we draw initial flight capacities based on the empirical distribution of the capacity remaining 120 days before departure. For every route-departure date combination, we simulate flights through departure 10,000 times. We do not endogenize connecting traffic demand. Instead, we handle connecting bookings as exogenous decreases in remaining capacity based on Poisson rates estimated using connecting bookings data. Consumer arrivals and demand come from our model estimates, and prices are determined by the heuristic. Realized demand depends on the capacity remaining. If demand exceeds remaining capacity, consumers are offered seats in the random order they arrive. Our counterfactuals allow for within-period price dispersion, facilitated by the protection levels set by the heuristic. For example, if a single seat remains at the lowest-available fare and is sold immediately, the next consumer to arrive within a period is offered the next fare with positive inventory remaining.

²⁷The psuedo-code for the heuristic, as well as an example, is detailed in Appendix A.

6.2 Pricing Department Unilateral Deviations

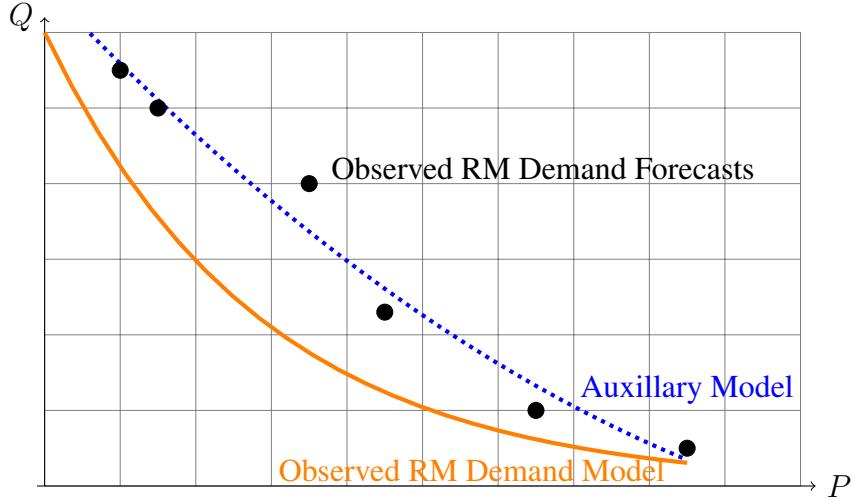

Studying department input decisions is complicated due to the richness of managerial decisions. In particular, the pricing department’s decisions involve high-dimensional, discrete inputs, and endogenizing all input decisions is not computationally feasible. Therefore, we consider a limited set of unilateral deviations.

Our pricing department counterfactual focuses on the coordination problem identified in Section 4. Recall that the pricing department commonly sets fares on the inelastic side of the RM department’s demand model. In this counterfactual, we implicitly assume that the pricing department uses the RM department’s demand model to remove fares that are on the inelastic side of the demand. The intuition for this counterfactual is that scarcity creates positive opportunity costs. If these opportunity costs are zero, the firm could solve a static revenue maximization problem such that the optimal price makes demand unit elastic. In the presence of scarcity, optimal prices will be higher. Therefore, we retain all fares on the elastic side of the internal demand model. These fares may be offered depending on forecasted and realized demand. We consider this pricing department deviation for every route-departure date-day before departure tuple and aggregate our results.

6.3 RM Department Unilateral Deviations

RM department actions are similarly rich; therefore, we again consider a limited set of unilateral deviations. We use an auxiliary model to capture all adjustments made by analysts in a parsimonious way. We then manipulate the estimated auxiliary model in counterfactuals. We use techniques from the empirical demand estimation literature to match the forecasting data to our Poisson discrete random coefficients demand model. Figure VII provides a graphical illustration of the intuition behind our approach. We project the forecasting data (“Observed RM Demand Forecasts” data in Figure VII) onto a flexible model (“Auxiliary Model” curve in Figure VII) rather than study millions of individual adjustments. Our approach allows us to re-estimate the same 235,000 parameters of our demand model using hundreds of millions of forecasting data points. We proceed in two steps.

Figure VII: Auxiliary Model of RM Department Decisions

Note: The figure shows a graphical representation of modeling RM department decisions. The (solid) orange line depicts the observed demand model. The black dots depict the final forecasts that are inputted into the heuristic. The (dashed) blue line denotes our auxiliary model, which takes the forecasting data and projects it onto a discrete random coefficients demand model.

First, we recalibrate the compound Poisson distributions using the passenger assignment algorithm managed by the RM department. This algorithm classifies all search activity (and purchases) as coming from a “business” or “leisure” traveler using an underlying probability model that varies by days before departure. We assume the same total intensity of consumer arrivals and recalibrate the composition of arriving customers ($\gamma_{t,r}$) as

$$\gamma_{t,r}^{\text{forecast}} = \frac{\sum \text{Arrivals}_{t,r}^B}{\sum \text{Arrivals}_{t,r}^B + \sum \text{Arrivals}_{t,r}^L},$$

where $\text{Arrivals}_{t,r}^B$ is the total number of arrivals classified as business for route r using the passenger classification algorithm (L is similarly defined). With these estimates, the adjusted arrival processes are $\hat{\lambda}_{t,d,r}\gamma_{t,r}^{\text{forecast}}$ for business passengers and $\hat{\lambda}_{t,d,r}(1-\gamma_{t,r}^{\text{forecast}})$ for leisure traffic. We label these Poisson rates $\tilde{\lambda}_{t,d,r}^B$ and $\tilde{\lambda}_{t,d,r}^L$.

Second, we recover preferences consistent with the RM department’s forecasts. The forecasts are quantity demand predictions for the flight (j), departure date (d), passenger type (ℓ), day before departure (d), and price level (p). We impose the same demand specification as in our demand model. Because the RM department uses a single-product demand model, we abstract from cross-price elasticities and assume arrival rates are equal to $\tilde{\lambda}_{t,d,r}^\ell$ for each flight

$j \in J_{d,r}$.²⁸ We match the forecast to the auxiliary model:

$$\tilde{Q}_{j,t,d,r}^\ell(p) = \tilde{\lambda}_{t,d,r}^\ell s_{j,t,d,r}^\ell(p). \quad (1)$$

Plugging in a different price, p' , results in another matched equation for the same forecast j, t, d, r . Importantly, these forecasts are unconstrained so that predictions are not censored. Taking logs of the Equation 1 and subtracting the log of the outside good share, we use the inversion of Berry (1994) to obtain²⁹

$$\log\left(\frac{\tilde{Q}_{j,t,d,r}^\ell}{\tilde{\lambda}_{t,d,r}^\ell}\right) - \log(s_{0,t,d,r}^\ell) = \log(s_{j,t,d,r}^\ell) - \log(s_{0,t,d,r}^\ell) = \tilde{\delta}_{j,t,d,r}^\ell.$$

This provides a linear estimating equation (suppressing subscripts), $\tilde{\delta} = X\tilde{\beta} - \tilde{\alpha}p + u$, where $\tilde{\beta}, \tilde{\alpha}^B, \tilde{\alpha}^L$ are preferences to be estimated.³⁰

We summarize our results of the auxiliary demand estimation in Table III. A key finding is that the forecasting data also suggests that demand is near unit elastic. However, there are key differences between these estimates and our demand estimates. We provide a route-level comparison of price coefficients to our demand estimates in Figure VIII. Each point is a route-specific comparison of parameter estimates. We find that the forecasting data suggests that leisure travelers are significantly more inelastic than our estimates imply—most routes fall above the 45 degree line in panel (a). The estimates for the business price sensitivity coefficient (panel (b)) are more similar, with roughly half the estimates falling below the 45-degree line. Figure VIII shows significant compression of the price coefficients estimated using the forecasting data in comparison to the heterogeneity in our model estimates. This is a consequence of the limited heterogeneity incorporated in the RM department's demand model—as discussed

²⁸Instead, we could assume arrivals are $\tilde{\lambda}_{t,d,r}^\ell/J$, so that each flight receives $1/J$ of arrivals. However, we find that this increases product shares and results in consumers estimated to be more price insensitive.

²⁹This inversion is only possible because the forecasting data are at the consumer-type level. Otherwise, we would have to use the contraction mapping in Berry, Levinsohn and Pakes (1995) and Berry, Carnall and Spiller (2006).

³⁰This approach results in an estimated " ξ " that also differs across consumer types through u . We set these residuals equal to zero and include our estimated ξ to be consistent with our demand model. We use the mean of the posterior for that observation, which is taken from our demand estimates. This does not greatly impact our findings, as the average difference in forecasted demand by replacing the u with ξ is 0.007 (sd = 0.11).

Table III: Auxiliary Demand Estimates Summary: Forecasting Data

Summary						
Elas	e	-0.986	0.196	-0.977	-1.097	-0.872

Note: The table reports parameter estimates for the 140 routes in the estimation sample conducted using the forecasting data. Reported here are aspects of the parameter estimates across routes.

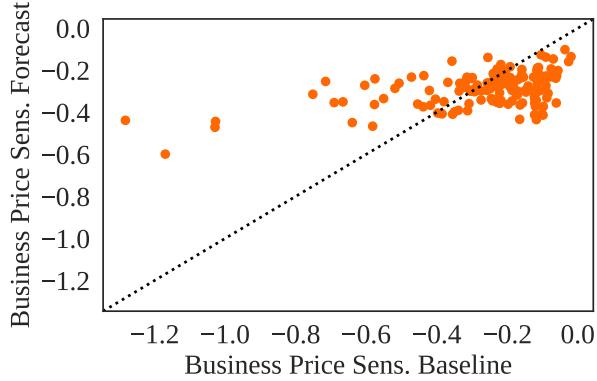

in Section 3, each route follows one of six parameter specifications, whereas our model has route-specific parameters.

Figure VIII: Price Sensitivity Comparison

(a) Leisure Price Sensitivity

(b) Business Price Sensitivity

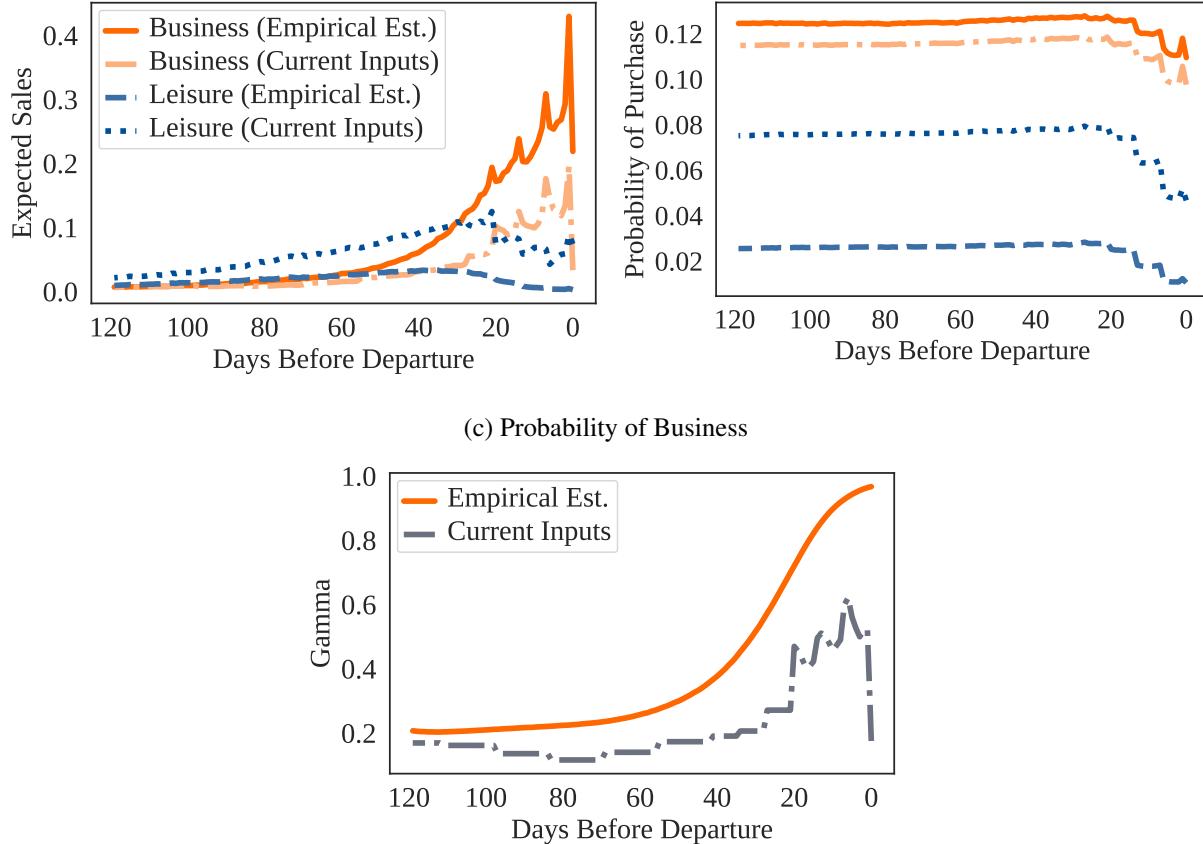

Note: Panel (a) shows a comparison of the posterior mean of the price sensitivity coefficients for the leisure consumer type versus the price coefficient for the leisure consumer type using the forecasting data. Each observation is a route. Also plotted is the 45-degree line. Panel (b) shows the same information, but plots on the price sensitivity coefficients for the business consumer type.

We compare demand predictions using our estimates and those obtained from the auxiliary model in Figure IX. Panel (a) shows expected demand for both consumer types over time,

panel (b) shows consumer-type flight-level choice probabilities over time, and panel (c) shows probability of a traveler being of the business type (γ) over time. While choice probabilities for business travel demand are similar (panel b), the forecasting data suggest a larger fraction of demand comes from leisure travelers than our demand estimates suggest (panel c).

Figure IX: Comparison of Demand Predictions

(a) Expected Booking Rates (b) Flight-Level Choice Probabilities

Note: For all plots, Empirical Est. refers to the demand estimates recovered in Section 5. Current Inputs refers to the estimates from the auxiliary model estimated from the forecast data. The plots show: (a) flight-level demand over time, (b) flight-level market shares over time, and (c) probability of business over time. Panels (a) and (b) share the same legend and separate business and leisure predictions.

With estimation of the auxiliary model complete, we turn to the set of unilateral deviations that we consider. As discussed in Section 4, the most common analyst adjustment is a scaling of the overall intensity of demand for multiple routes and departure dates simultaneously. This is analogous to adjusting the arrival rates of the model, which motivates how we counterfactually study RM department decisions. We study how RM department decisions affect outcomes by scaling down/up the demand predicted by the estimated auxiliary model by a fac-

tor χ . The scaled forecasts are then used as an input to the pricing heuristic. We consider $\chi \in \{0.25, 0.5, 0.75, \dots, 3.0\}$. A scaling factor less than 1.0 reduces the observed, persistently upward forecasting bias.

6.4 Analysis of Department Input Decisions

We report counterfactual market outcomes for the pricing department unilateral deviation in Table IV, where we normalize outcomes under current inputs to 100 (leisure and business consumer surplus, quantity sold, revenues, and welfare). We find the potentially surprising result that coordinating the fare menus to the RM department’s demand model does not increase revenues—in fact, we find that it reduces revenues by 0.9%.³¹

The pricing department unilateral deviation does not increase revenues for a few reasons. First, this counterfactual entails coordinating to a biased input (RM demand model). We find that this counterfactual removes some fares that are on the elastic side of our estimated demand model. We find that this unilateral deviation tends to increase prices early on and results in an 8% decrease in output. Second, the pricing department’s decisions interact with a heuristic that is also subject to bias. Removing fares that are on the inelastic side of the internal demand model affects the heuristic in complex ways: a single fare decision can affect future protection levels (and hence, future prices), but the heuristic does not consider these impacts because it is myopic. As a result, it can be revenue maximizing for the pricing department to include some fares that are on the inelastic side of the demand curve.

Given how fare decisions interact with other inputs and the heuristic, characterizing the optimal pricing menu, even when abstracting from competitive forces, is difficult. While the number of fares the pricing department can choose is limited due to protocols used in the industry (Vinod, 2021), reflecting an environment constraint on the organization (Siggelkow, 2001), it may be revenue maximizing for the firm to use coarse pricing menus as it disciplines how much market segmentation the heuristic believes it will achieve. In addition, adjusting or adding fares has an unclear effect on pricing decisions, because these inputs are then passed to the RM department from which forecasts are built. The pricing department may be acting optimally for

³¹We find that this unilateral deviation results in increased revenues for nine out of 140 routes.

the firm given the information it has access to in the spirit of Simon (1956).

Table IV: Pricing Department Deviation Counterfactual

Counterfactual	CS_L	CS_B	Q	Rev	W
Observed Inputs	100.0	100.0	100.0	100.0	100.0
Pricing Department Deviation	77.9	100.4	91.9	99.1	99.0

Note: In the counterfactual shown in the first row, we approximate current pricing practices and aggregate results across routes. Results are then normalized to 100. The counterfactual shown in the second row summarizes the pricing department deviation counterfactual relative to the first row.

Next, we consider RM department unilateral deviations, which we summarize in Table V. We report market outcomes for reductions in the forecast bias (χ), normalized to the current forecast bias. Our central finding is that unilateral bias reduction reduces revenues. Therefore, relative to the set of possible deviations that we consider, it is revenue maximizing for the RM department to bias its input, given the pricing department's choices and the heuristic. Moreover, reducing forecast bias actually increases misallocation by shifting the distribution of sales to earlier arrivals and leaving fewer seats (driven by increased early sellouts) for price insensitive, late-arriving consumers. Leisure consumers benefit from smaller forecasting biases, and business consumers are made worse off.

Table V: RM Department Deviation Counterfactual, Decreasing Bias

Counterfactual	CS_L	CS_B	Q	Rev	W
Scale = 0.25	104.9	98.9	101.1	98.7	98.9
Scale = 0.50	103.4	99.2	100.8	99.1	99.2
Scale = 0.75	101.8	99.6	100.4	99.5	99.6
Observed Inputs	100.0	100.0	100.0	100.0	100.0

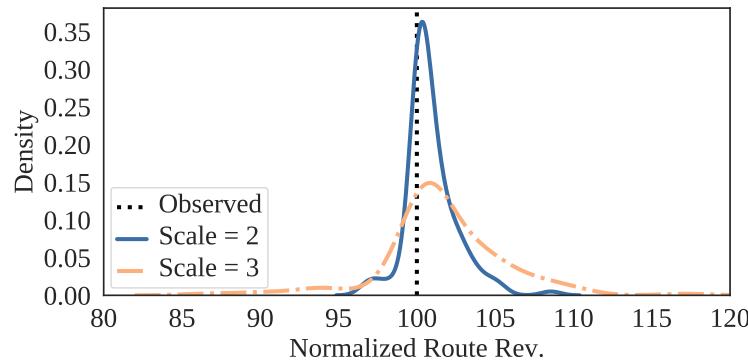

Note: The last row reports normalized (to 100) outcomes under current pricing practices. The first through third rows summarizes counterfactuals where the auxiliary model demand is scaled by the reported value. Results are reported relative to current pricing practices.

We also investigate RM department unilateral deviations that further increase forecast bias. In Figure X, we plot the distribution of counterfactual route revenues under a forecast bias of 100% and 200%, respectively. We find that biasing demand forecasts upward results in relatively small revenue gains. For example, overstating demand by 100% leads to a 1% increase in firm revenues. Further increasing the bias yields quantitatively similar revenue effects, but

also increases the dispersion in revenues across routes (see the greater variance in “Scale = 3” versus “Scale = 2” in Figure X) and would make forecasts less informative if used outside of the inventory allocation process.

Crucially, our counterfactuals offer insights into the persistence of pricing biases within a sophisticated firm: unilateral bias reduction reduces revenues, and observed department decisions are consistent with revenue maximization, provided that we rule out extreme forecast bias. In the next section, we consider an alternative model of supply to investigate if assuming that the firm is a unitary, rational decision-maker yields similar predictions of counterfactual market outcomes and welfare.

Figure X: RM Department Deviation Counterfactual, Increasing Bias Across Routes

Note: The figure shows kernel density estimate (KDE) plot of counterfactual revenues at the route level under alternative forecast bias. Scale = 2 implies a forecast bias of 100%, and Scale = 3 implies a forecast bias of 200%. Route revenues are normalized based on current pricing practices, e.g., 105 means a 5% revenue increase relative to observed inputs.

7 Comparison to the Firm as a Unitary Decision-Maker

Our final counterfactual compares market outcomes under observed pricing practices to those that arise by simulating the prices the firm would charge if it were a unitary entity and maximized revenues accordingly. This allows us to measure if counterfactual welfare is sensitive to abstracting from organizational structure and the use of heuristics.

We simulate prices based on the following dynamic program (DP) (j, d, r subscripts suppressed)

$$V_0(C_0) = \max_{\{p_t\}_{t=0}^T} \mathbb{E} \sum_{t=0}^T p_t \cdot \min \left\{ \tilde{q}_t(p_t), C_t \right\},$$

such that $C_{t+1} = C_t - \min \{\tilde{q}_t(p_t), C_t\}$, unsold units are scrapped, and $C_0 \geq 0$ is given. This DP differs from observed pricing in significant ways. First, the DP fully internalizes dynamic opportunity costs, whereas the observed heuristic solves a static problem. Second, the DP also fully considers static opportunity costs, whereas the observed heuristic abstracts from all forms of product substitution. Third, the dynamic program naturally “solves the coordination” problem that we identified where department inputs (and the use of the heuristic) can lead to pricing on the inelastic side of demand. By solving a dynamic program, prices are always on the elastic side of demand (Gallego and Van Ryzin, 1994; Betancourt et al., 2023).

Although the DP is well-defined for an arbitrary number of flights, in practice, solving DPs in non-stationary, finite horizon environments is computationally challenging. For example, routes with greater than two flights contain on average 40 billion states. Therefore, we restrict our analysis to routes with at most twice daily service. While we cannot characterize market outcomes under the DP for routes with more than two flights a day, larger routes involve the same economic forces.

We make two modeling choices in implementing this counterfactual. First, we use our demand estimates in lieu of the auxiliary forecasting estimates. This mimics standard practices in empirical work of first estimating demand and then counterfactually simulating market outcomes. Second, we retain discrete prices for not only computational reasons, but also to preserve the support of prices consumers typically face. Therefore, we quantify how the distribution of fares decided by the pricing department is affected by assuming prices are chosen according to the DP.

We construct the fare menus as follows. We define the lowest price on the menu to be the fare at which demand is unit elastic on the day before departure with the most price-sensitive demand (typically the earliest period). We specify the highest fare on the menu to be the most expensive economy-class fare observed in the data. All observed fares between the minimum and maximum are retained.

In Table VI, we report counterfactual results comparing the DP model to observed practices, which we have normalized to 100 in an analogous way to Table IV. Our key finding is that if the firm were a unitary, rational decision-maker, market outcomes would be significantly different

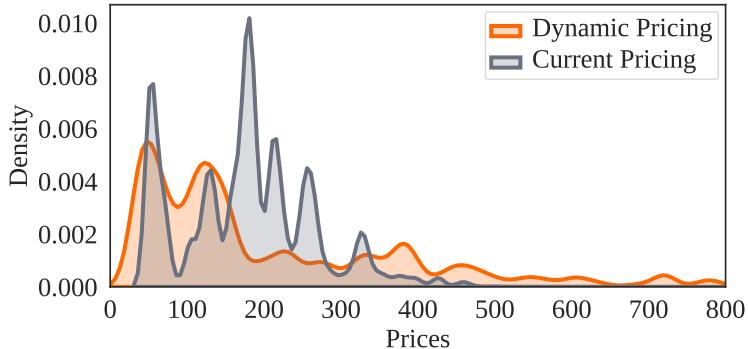

Table VI: Counterfactual Estimates under a Dynamic Pricing Model

Counterfactual	CS_L	CS_B	Q	Rev	W
Observed Inputs	100.0	100.0	100.0	100.0	100.0
Dynamic Pricing Model	108.9	70.6	86.1	112.9	89.1

Note: The table summarizes the counterfactuals comparing current pricing practices to those that arise from assuming that the firm solves a dynamic program (DP). Market outcomes for each route are normalized based on outcomes using observed inputs.

than those observed. Figure XI presents the distribution of prices offered under the DP to those set by the heuristic and highlights the greater segmentation obtained under the DP. Optimal dynamic prices result in increased price targeting that benefits leisure consumer surplus (by 9%) due to lower prices early on. Business consumer surplus is lower (by 29%) due to increased price targeting. The magnitudes are significant. Two additional findings are notable. First, the DP results in higher revenues (by 13%) than those observed. Second, if the firm were to adopt the DP, we estimate that total welfare would decrease by a significant margin (by 11%).

Figure XI: Comparison of Observed Pricing Practices to DP

Note: The figure shows kernel density estimate (KDE) of prices under observed inputs using the heuristic EMSRb versus those that arise from assuming that the firm solves a dynamic program. The figure contains all prices for routes with at most two daily flights during the sample period.

7.1 Discussion

Our results show that airline pricing is not well approximated by a model that abstracts from organizational structure and the use of heuristics. Incorrectly assuming that the firm is a rational, unitary decision-maker results in mismeasuring counterfactual welfare. The gap in counterfactual welfare under observed practices compared to assuming the firm solves a dynamic pricing program is significant.

There is a second channel by which not accounting for the fact that prices are set through decomposition and heuristics can affect estimates of welfare and markups. Supply restrictions are often used to estimate demand (e.g., Berry, Levinsohn and Pakes, 1995). Conlon and Gortmaker (2020) show that these restrictions provide significant identifying power. However, if the correct model of supply involves the use of heuristics and delegated decision-making, but a model of the firm as a unitary decision-maker is instead imposed, the resulting demand estimates will be biased.³² Therefore, our findings are useful for both designing counterfactuals and providing guidance on what inferences we draw from observed firm behavior.

While we believe that our insights likely apply to many important industries where firms solve complex problems, our results are subject to some important caveats. First, our analysis abstracts from competition. The relevant dynamic game is difficult to formalize because the heuristic used does not consider competition when allocating inventory and its inputs are chosen by multiple teams. Second, we take network planning decisions as given. These decisions interact with other department input decisions in complex ways within the heuristic.³³ Endogenizing network planning decisions creates additional complexity because departments respond to these decisions. For example, RM analysts may decide to oversell a flight by a particular number of seats, which inherently depends on network planning capacity choices.³⁴ Third, departments may have additional considerations that impact decision-making, even if they are not explicitly modeled internally. For example, internal presentations highlight that load factors serve as a performance indicator (KPI) in addition to revenues. An emphasis on output could dissuade

³²We demonstrate that this is also true using our data in Appendix D.5. Intuitively, if we assume prices are set by a rational, unitary decision-maker, then demand must at least be unit elastic. However, both our and the firm's demand estimates suggest that demand is often inelastic. In order to rationalize observed prices as "optimal," this requires making demand more elastic, decreasing markups (over opportunity costs), and understating consumer surplus (by a factor of four).

³³While relaxing capacity constraints is always beneficial in the dynamic programs we simulate—because the associated value functions are monotonic in capacity (Gallego and Van Ryzin, 1994; Betancourt et al., 2023)—this is not true given the pricing heuristic used by the firm. In particular, if the lowest fares on the menu are in fact on the inelastic side of demand (as we document in Section 4), then an increase in capacity could cause the heuristic to more often default to prices that are not revenue maximizing, reducing revenues.

³⁴These adjustments may be optimal for the firm. Alternatively, these adjustments may reflect incentive conflicts that we do not capture in our analysis. If departments have competing objectives, modeling the organization and what managers do (Gibbons and Henderson, 2012) may be necessary to rationalize observed behavior. How to structure incentives depends on the complexity of the problem (e.g., Bajari and Tadelis, 2001). However, our insight that observed outcomes are inconsistent with a model of the firm as a rational, unitary decision maker remains.

departments from adopting practices that have the potential to reduce load factors. Nevertheless, integrating marginal cost metrics into a heuristic designed to optimize revenue might lead to offsetting effects. Finally, we note that our findings are not inconsistent with departments having concerns regarding long-term demand and/or loyalty.

8 Conclusion

This paper establishes that relaxing the assumption that firms act as if they are single agents and maximize profits accordingly is critical for understanding how firms set prices. We proceed in three steps. First, we document the extent to which large firms decompose the problem of pricing to distinct departments. Using online job listings and professional networking profiles, we show that cruises, car rentals, ride share companies, hotels, and all major airlines rely on an organizational structure in which departments have distinct pricing-related decision rights. Second, using data and internal models from a large U.S. airline, we establish that pricing is subject to multiple biases that affect all routes, regardless of market structure. Third, using a subsample of single-carrier routes, we show that observed pricing decisions are largely consistent with departments choosing inputs to maximize revenues around the observed heuristic but diverge from a model where we assume the firm is a single, rational entity. We estimate that if the firm were a unitary decision maker, welfare would decline as a result of increased price targeting, a focus among policy makers given the rise of big data (CEA, 2015).

Our results have important implications for how we model supply. We provide direct evidence using internal models and data that pricing at a sophisticated firm does not fully internalize static and dynamic opportunity costs. An analysis that assumes opportunity costs are fully accounted for when analyzing data or counterfactually simulating market outcomes will obtain biased estimates of markups and welfare if pricing is set through decomposition and heuristics. Imposing alternative supply-side assumptions that capture how firms simplify the complex problems they face may provide better approximations of welfare and market power. This is especially relevant for the study of competitive interactions. Indeed, existing competitive frameworks that assume firms are unitary decision-makers fail to predict observed, post-merger

prices (Weinberg and Hosken, 2013). Moreover, recent empirical evidence suggests that more firms are adopting pricing heuristics (Assad et al., 2023; Calder-Wang and Kim, 2023). Accurately accounting for the capabilities and constraints of heuristics and how managers decide their inputs is critical for understanding how efficiently markets operate.

A Additional Details on the Pricing Heuristic

The firm optimizes remaining inventory using a heuristic called Expected Marginal Seat Revenue-b or EMSRb (Belobaba, 1987). The heuristic requires three main inputs: a discrete set of fares, demand forecasts for each fare in every period, and a capacity constraint. The heuristic is a generalization of Littlewood’s Rule to multiple (> 2) fares. It avoids solving a dynamic pricing problem by considering a sequence of static decisions. The heuristic does not decide a single price, but rather allocates the maximum number of seats it is willing to sell at each fare. The lowest-available fare (LAF) is the least expensive fare that receives a positive inventory allocation. If all inventory allocated to this fare sells before re-optimization occurs, the next highest fare with positive allocation becomes the LAF. All flights are reoptimized daily, and all flights, regardless of market structure, are priced using this heuristic.

The key insight and simplification of the heuristic is that it assumes consumers will arrive in increasing order of willingness to pay. It partitions demand along the discrete set of fares and computes protection levels that ensure seats are saved for higher willingness to pay customer segments. For example, if forecasted demand at a high price is high, it may “protect” most remaining capacity for this consumer segment and “reject” forecasted demand at a low price. That is, it will allocate fewer seats to lower fares and more seats to higher fares.

A.1 Littlewood’s Rule

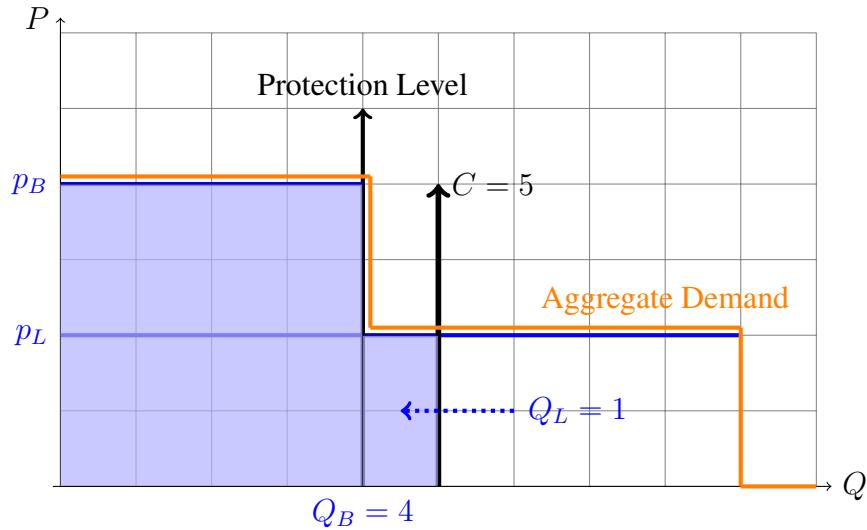

Littlewood (1972) proposed the first inventory allocation rule for the case where there are two consumer segments and two prices. We refer to the two consumer segments as leisure (more elastic) consumers and business (less elastic) consumers. Littlewood’s rule assumes that business consumers arrive after leisure consumers. The rule sets a protection level (PL) on the number of seats reserved for business consumers at the higher fare. Simultaneously, it limits the number of seats offered to leisure consumers who are assumed to arrive first. With C seats remaining and a CDF of business consumer arrivals, Littlewood’s rule is

$$p_L = \left(1 - \Pr(Q_H \leq PL)\right)p_H \iff 1 - \frac{p_L}{p_H} = \Pr(Q_H \leq PL).$$

Letting $F_H := \Pr(Q_H \leq PL)$, the protection level can be found by solving $PL = F_H^{-1} \left(1 - \frac{p_L}{p_H}\right)$. This is equivalent to solving the first-order condition of the associated constrained maximization problem.

Figure A.12 illustrates the intuition for how protection levels segment demand without uncertainty. There are two fares, p_L and p_H , and the capacity constraint is five. Given the aggregate demand curve plotted, it is optimal to set the protection level equal to four and only allow one consumer to purchase at p_L . Any other protection level would reduce revenues. For example, $PL = 3$ would allow two purchases at p_L . Setting $PL = 5$ would cause a seat to go unfilled. When allocating remaining capacity, the firm adds uncertainty into its forecasts. While work in operations commonly uses stochasticity, which is not micro-founded—e.g., adding normal errors around the demand curve (Belobaba, 1987)—we provide a micro-foundation for this uncertainty by using Poisson arrivals.

Figure A.12: Protection Level Intuition

Note: In this protection level illustration, aggregate demand is plotted in orange. With five seats remaining, it is optimal to protect four seats for B customers, and only allow one L customer to purchase.

A.2 EMSRb Algorithm

EMSRb applies the insight of Littlewood's rule to the scenario where there are more than two consumer segments/fare classes. When computing a given fare's protection level, it considers not only the demand at that fare, but also the demand at fares above that level. It calculates an

artificial fare called the “super bucket” that is simply the average expected revenue per passenger who is willing to pay that fare or higher (see Figure A.13 for an illustration of this calculation with two segments and fare classes). This is what makes the algorithm a heuristic, i.e., that it differs from an economic model. Once this bucket is formed, Littlewood’s rule can be applied because there are now just two fares and two segments. Note that the super bucket represents “business consumers” in Littlewood’s rule, as the consumer segments below the current fare have lower willingness to pay. The protection level for that segment is determined, and the process repeats down the demand curve. Critically, the heuristic maintains the assumption that consumers arrive in ascending order of their willingness to pay.

Let K denote the number of fares and assume that fares are sorted such that $p_1 < p_2 < \dots < p_K$. Demand for each class k follows distribution F_k . For example, in our empirical model, the demand for each fare class is distributed Poisson with mean $\mu_k(p_k)$. Note that assuming demand is Poisson simplifies this calculation, as the sum of independent Poisson distributions is itself Poisson.

We write the pseudo-code for EMSRb below. The airline runs the heuristic each day before departure (t). In the pseudo-code below, PL are the protection levels. The booking limits BL define the number of seats that can be sold at each fare level. For example, if there are three fares, p_H, p_M, p_L , potential protection levels could be $PL = (3, 4, \cdot)$. There is no protection level for the lowest fare because that segment is provided by all the remaining seats that are not protected. For example, if $C = 10$, $PL = (3, 4, \cdot)$ implies that $BL = (10, 7, 6)$. That is, six seats are allocated to p_L , seven are allocated to p_M , and the firm is willing to sell all seats at p_H .

Algorithm 2 Psuedo-code for the Firm's Pricing Heuristic used in Counterfactuals

for $k = K, K - 1, \dots, 2$ **do**

- i) Calculate aggregate future demand for fare k , $\mu_k = \sum_{i=t}^T q_i(p_k)$,
- ii) Calculate partitioned demand, which is the difference in demand between p_k and p_{k+1} where $p_{K+1} = \infty$ as $\text{PD}_k := \mu_k - \mu_{k+1}$, and partitioned revenue for fare k as $\text{PR}_k := p_k \cdot \text{PD}_k$,
- iii) Calculate super revenue, $\text{SR}_k := \sum_{b=k}^K \text{PR}_b$, and the super bucket, $\text{SB}_k := \text{SR}_k / \mu_k$,
- iv) Calculate the fare ratio as $\text{FR}_k := p_{k+1} / \text{SB}_k$, and use Littlewood's Rule to calculate protection level for fare k , $\text{PL}_k := F_{\text{SB}}^{-1}(1 - \text{FR}_k) \in \mathbb{N}$, where $F(\cdot)$ is the discrete distribution of the super bucket,
- v) Calculate the booking limit such that $\text{BL}_K = C$ and set

$$\text{BL}_{k+1} := \max \left\{ C - \text{PL}_k, 0 \right\} \in \mathbb{N}.$$

end

A.2.1 Fare Class Demand

Aggregate future demand at p_k , μ_k , has a closed form under the assumption of Poisson demand. In our model, $q_{j,t}(p) = \exp(\lambda_t + \lambda_d)s_{j,t}(p)$. Note that in our empirical application, p is a vector of the prices of all flights in the market. Because EMSRb assumes there is a single product, we implement EMSRb under the additional assumption that the firm believes other flights will be priced at their historic average over the departure date and day before departure. We construct residual demand for j , $s_{j,t}(\cdot)$, which enter the heuristic.

Demand at a higher fare class, $k + 1$, is equal to $\exp(\lambda_t + \lambda_d)s_{j,t}(p_{k+1})$. Therefore, only $\exp(\lambda_t + \lambda_d)[s_{j,t}(p_k) - s_{j,t}(p_{k+1})]$ additional consumers are willing to purchase moving from price $k + 1$ to k . EMSRb aggregates all future demand by fare class. Because the sum of Poisson distributions is itself Poisson, total partitioned demand for fare-class k at time $t \leq T$ is given

by (dropping the j subscript)

$$\text{PD}_k = \sum_{i=t}^T \exp(\lambda_i + \lambda_d) [s_i(p_k) - s_i(p_{k+1})],$$

The super bucket can be calculated as

$$\begin{aligned} \text{SB}_k &= \frac{\sum_{b=k}^K p_b \text{PD}_b}{\sum_{i=t}^T q_i(p_k)} \\ &= \frac{\sum_{b=k}^K p_b \cdot \left(\sum_{i=t}^T \exp(\lambda_i + \lambda_d) [s_i(p_b) - s_i(p_{b+1})] \right)}{\sum_{i=t}^T \exp(\lambda_i + \lambda_d) s_i(p_k)} \end{aligned}$$

A.2.2 Example of EMSRb

Consider a single product, sold over $T = 3$ sequential markets, with three fares, $p = \{0.50, 1.50, 3.0\}$, measured in hundreds of dollars. Assume demand is not changing over time and distributed Poisson, i.e., $q_t \sim \text{Poisson}(\lambda \cdot s(p))$, such that $s : \{0.50, 1.50, 3.0\} \rightarrow \{0.2, 0.1, 0.05\}$, and $\lambda = 10$ each period. Initial capacity is $C = 10$.

Table A.7 below shows all objects required to obtain the protection levels and booking limits of EMSRb in the first period. Within the table are superscripts, from a to h . In Table A.8, we provide the calculations and mathematical expressions corresponding to those letters.

Table A.7: EMSRb Example

Fare	Q	PD	PR	SR	SB	Fare Ratio	PL	BL
3	1.5^a	1.5	4.5	4.5	3	0.5	1^g	10
1.5	3	1.5^b	2.25	6.75^d	2.25	0.222^f	4	9^h
0.5	6	3	1.5^c	8.25	1.375 e			6

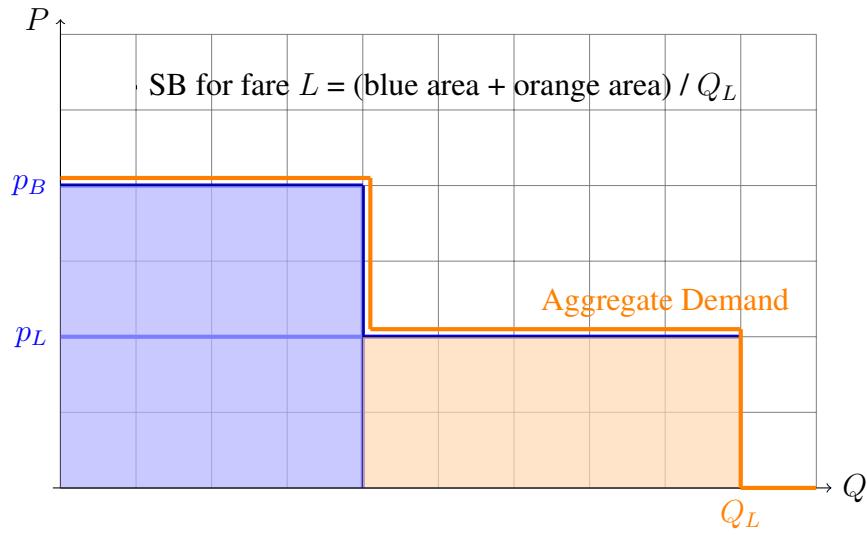

Note: Columns correspond to (in order): fare, aggregate demand, partitioned demand, partitioned revenue, super revenue, super bucket, fare ratio, protection level, and booking limit.

Table A.8: EMSRb Example Computations

Letter	Calculation	Expression
<i>a</i>	$0.05 \cdot 10 \cdot 3$	$Q = s(3) \cdot \lambda \cdot T$
<i>b</i>	$3 - 1.5$	$Q(1.5) - Q(3)$
<i>c</i>	$0.5 \cdot 3$	$0.5 \cdot PD(0.5)$
<i>d</i>	$2.25 + 4.5$	$PR(1.5) + SR(3)$
<i>e</i>	$8.25/6$	$SR(0.5)/Q(0.5)$
<i>f</i>	$0.5/2.25$	$0.5/SB(1.5)$
<i>g</i>	InversePoisson($1 - .5, 1.5$)	InversePoisson($1 - \text{Fare Ratio}(3), Q(3)$)
<i>h</i>	$10 - 1$	$C - PL(3)$

Note: The first column denotes the superscripts marked in Table A.7. The second column denotes the calculation required to compute the corresponding letter. Finally, the last column denotes the mathematical expression behind the calculation. Remaining numbers in the last column denote fare values.

Figure A.13: Super Bucket Calculation Illustration

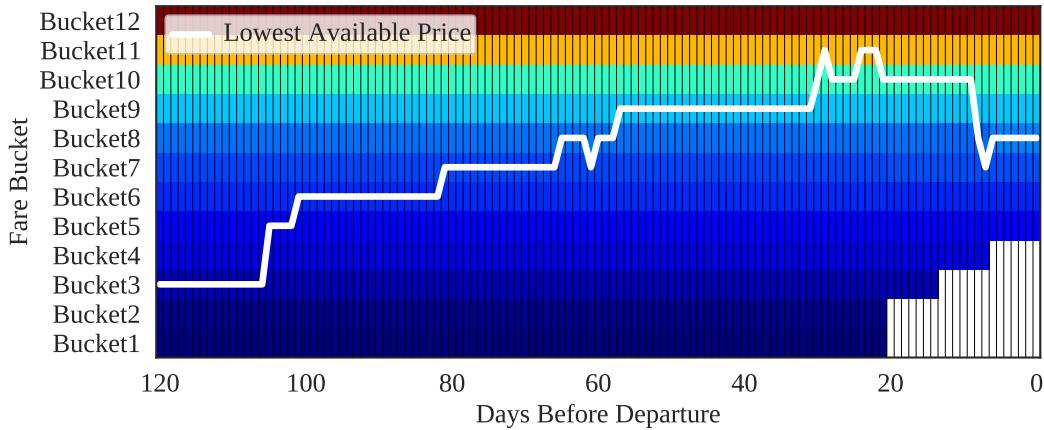

Note: The figure illustrates the calculation of the super bucket at fare p_L . Note if all consumers had the same willingness to pay, the super bucket would simply be equal to p_L . However, there is an additional segment, willing to pay more than p_L . This is the H segment. The super bucket calculates total revenue above p_L and divides by Q_L .

A.2.3 Empirical Example of EMSRb

We show an example outcome of EMSRb in Figure A.14. On the vertical axis, we note the discrete set of fares set by the pricing department, with bucket one being the least expensive and bucket twelve being the most expensive. We do not report the actual fare values. There is no variation in the prices for each fare class over time. In the bottom right of the graph, the white space shows that the pricing department has restricted the availability of the lowest fares close to the departure date. That is, there are advance purchase requirements for the lowest fare classes. We do not plot the network planning department's choice of C , nor the demand forecasts themselves. The white line traces out the LAF determined by EMSRb over time. As the graph shows, the LAF is generally increasing over time—prices for the flight increase. The LAF for this particular flight reaches eight unique classes before departure.

Figure A.14: Fare Bucket Availability and Lowest Available Fare

Note: The figure shows a plot of fare availability over time as well as the active lowest available fare. Bucket1 is the least expensive bucket; Bucket12 is the most expensive bucket. The color depicts the magnitude of fares—blue are lower fares, red are more expensive. White space denotes no fare availability. The white line depicts the lowest available fare.

B Route Selection and Summary Analysis

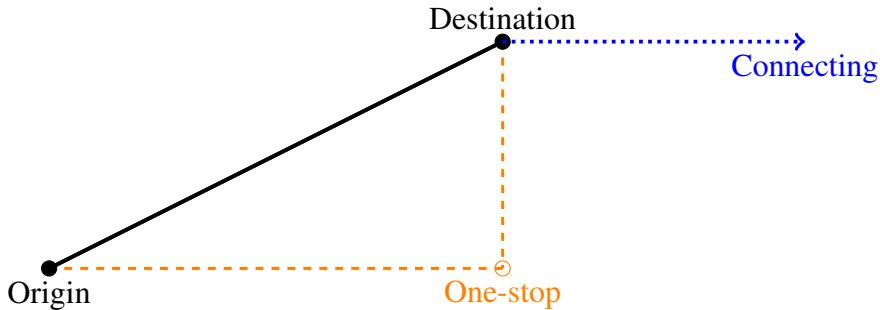

We select routes based on the following criteria that we apply to publicly available data. Because the DB1B contains a 10% sample of passenger tickets flown, we scale passenger volume by $10\times$ to match total travel volume. We use the following selection criteria:

- i) Combine nearby airports to “city codes.” More specifically, we combine the following

airports: (HOU, IAH); (DFW, DAL); (BWI, DCA, IAD); (MDW, ORD); (EWR, JFK, LGA); (LAX, LGB, ONT, SNA, BUR, SBA); (SFO, OAK, SJC);

- ii) Remove routes where over 10% of passengers fly on carriers that do not make their tickets available on third-party websites;
- iii) Retain routes where at least 25% of passengers fly on the airline we study;
- iv) Retain routes where at least 750 passengers fly quarterly;
- v) Remove routes where fewer than 500 passengers fly nonstop;
- vi) Retain routes where the airline we study provides daily nonstop service.

Figure B.15: Nonstop, One-stop and Connecting Traffic

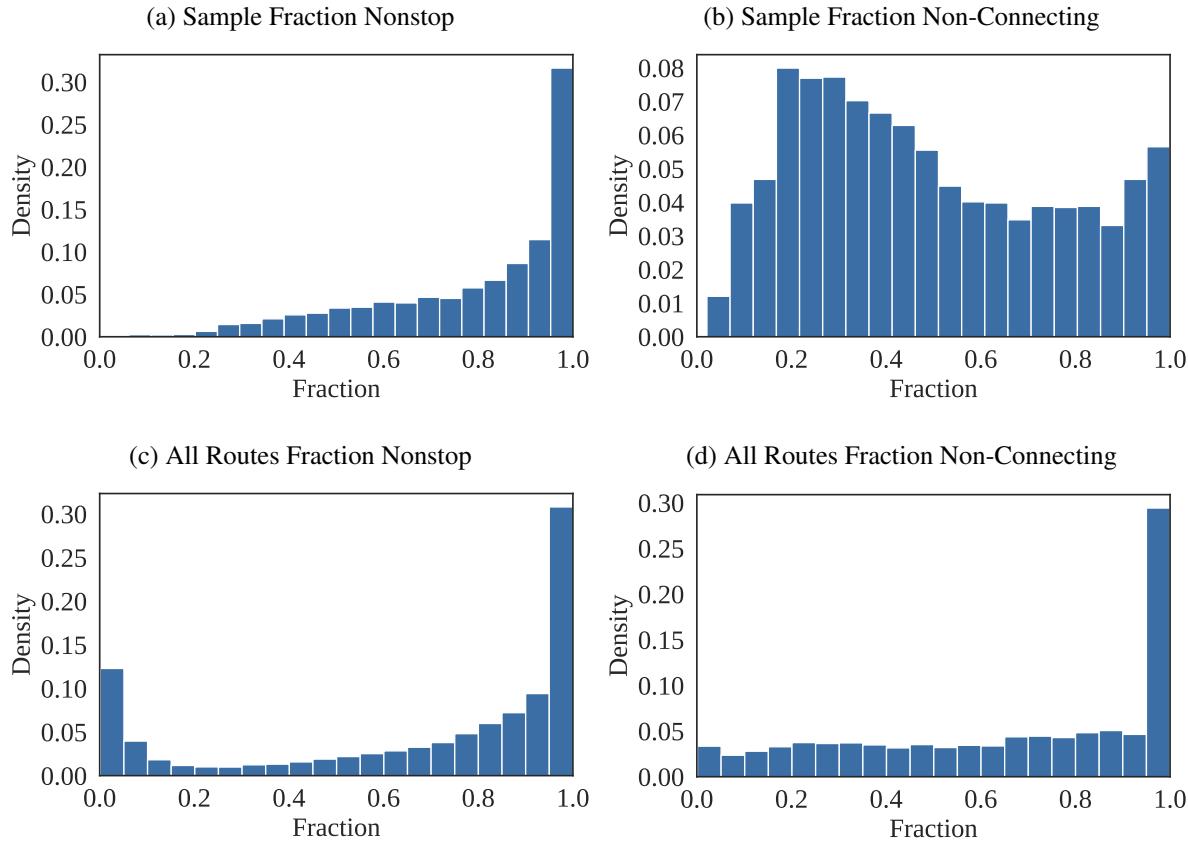

Note: We use the term nonstop to denote the solid black line, or passengers solely traveling between (Origin, Destination). Unless otherwise noted, we will use directional traffic, labeled $O \rightarrow D$. Non-directional traffic is specified as $O \leftrightarrow D$. The blue, dashed lines represent passengers flying on $O \leftrightarrow D$, but traveling to or from a different origin or destination. Finally, one-stop traffic are passengers flying on $O \leftrightarrow D$, but through a connecting airport.

We perform these operations for the first three quarters of the U.S. Department of Transportation's O&D Data Bank (DB1B) separately and take the union of routes. We then calculate the fraction of route (origin-destination) traffic flying nonstop across quarters. More precisely, we calculate directional traffic flows from a potential origin and destination pair that is served nonstop by our air carrier (see Figure B.15). We calculate the fraction of traffic flying from $O \rightarrow D$ nonstop versus flying via a one-stop connection. This compares the solid black line to the dashed orange line. Given the resulting set, we sort routes based on the fraction of passengers flying nonstop (decreasing). We select the first 470 origin-destination pairs from this list.

We also calculate the percentage of traffic that is not connecting. This is the fraction of traffic on the black line in Figure B.15 versus the total traffic that includes all potential dotted blue lines. We do not select routes based on the percentage of traffic that is not connecting because it is negatively correlated with the percentage of traffic flying nonstop, meaning it is difficult to find routes where both percentages are high. The former defines what fraction of seats on the plane we study, whereas the latter is critical for defining the choice set.

Figure B.16: Route Selection Using Bureau of Transportation Statistics Data

Note: The figure shows density plots over the fraction of nonstop traffic and the fraction of non-connecting traffic for the selected routes using the 2018-2019 DB1B data. Sample routes refers to the 470 routes in our sample; all routes refers to all routes across all carriers in the DB1B.

Figure B.16 presents summary distributions of the two metrics for the routes (ODs) in our sample and the entire set of domestic routes. The top row measures the fraction of nonstop and connecting traffic for tickets sold by our carrier. The left plot shows that, conditional on the air carrier operating nonstop flights between OD, an overwhelming fraction of consumers purchase nonstop tickets instead of purchasing one-stop connecting flights. The right panel

shows that fraction of consumers who are not connecting to other cities either before or after flying on segment OD. There is significant variation across markets, with the average being close to 50%.

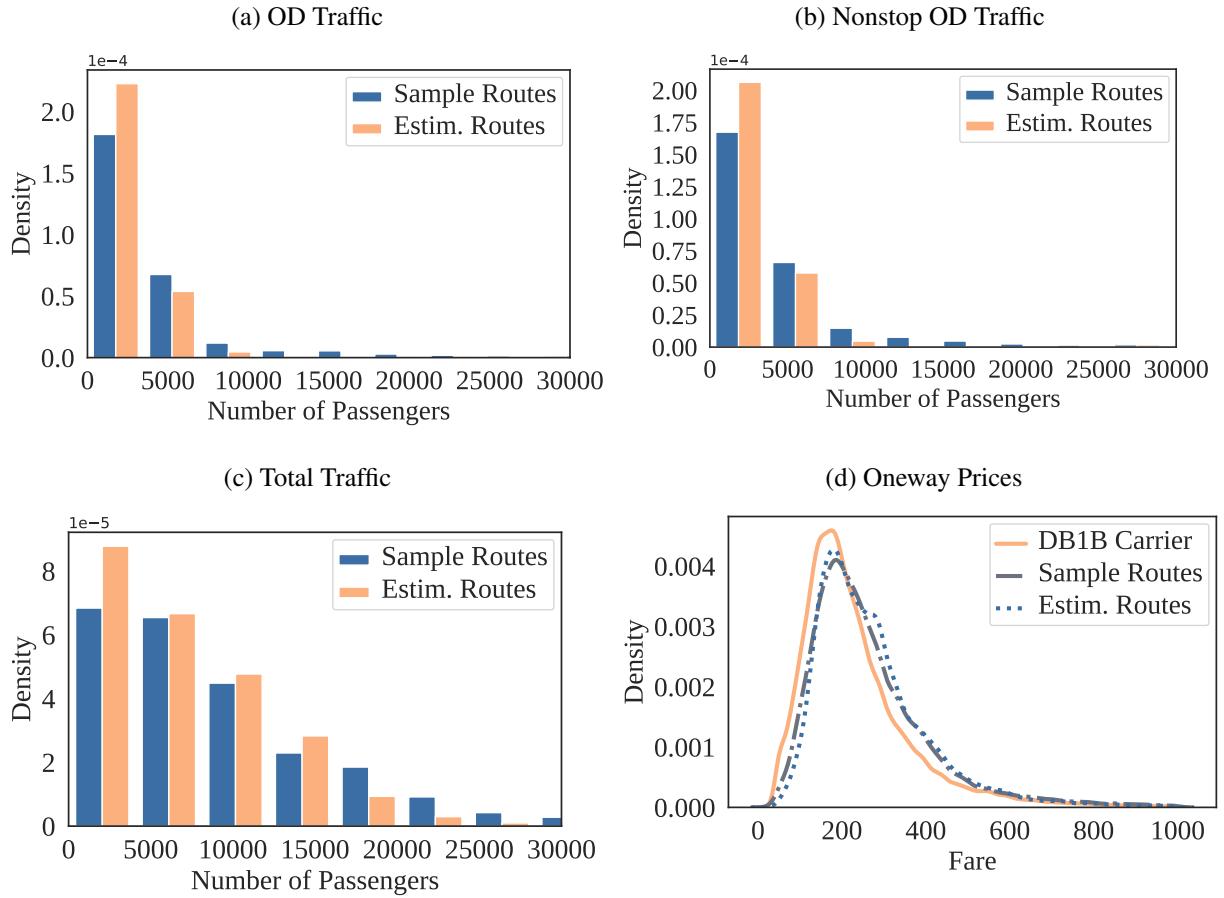

The bottom panel repeats the statistics but replaces the denominator of the fractions with the sum of traffic flows across all air carriers in the DB1B. Both distributions shift to the left because of the existence of competitor connecting flights and sometimes direct competitor flights. In nearly 60% of the markets we study, our air carrier is the only firm providing nonstop service. Our structural analysis will only consider single carrier markets.

B.1 Estimation Sample Comparison

Our estimation sample contains 140 routes. We use two selection criteria. First, we remove routes in our sample that contain nonstop competition. Second, we randomly select 140 routes from the resulting set of 280.

Table B.9 summarizes traffic flows across the data samples. Compared to all routes in our data set, single-carrier only routes and our estimation routes tend to be smaller in terms of total number of passengers. Other statistics, including the fraction of traffic traveling nonstop and non-connecting are similar. Figure B.17 presents histograms of passenger counts and kernel density estimates of prices for our entire data sample versus our estimation data sample. In panel (a), we plot origin-destination traffic (the black and orange lines in Figure B.15). In panel (b), we plot nonstop traffic (the black line in Figure B.15). In panel (c), we plot total traffic (the black and blue lines in Figure B.15). In panel (d) we plot the density of prices for our airline, the entire data sample, and the estimation data sample as three separate lines. Finally, in Figure B.18, we recreate Figure B.16 and compare the fraction of traffic which is nonstop and which is non-connecting, separating the estimation sample from the entire data sample.

Figure B.17: Sample vs. Estimation Sample Route Passenger Count and Fare Comparison

Note: The figure includes: (a) Count of quarterly OD passenger traffic; (b) Count of quarterly OD passenger traffic flying nonstop; (c) Count of quarterly total OD traffic, inclusive of onward connections; and (d) Fares per passenger. DB1B carrier means all routes served by the airline in the 2018–2019 DB1B; Sample routes means the 470 routes in our sample; Estimation routes means the 140 routes in our estimation sample. Panels (a)–(c) present histograms with few outliers greater than 30,000 not depicted (between 0–5% of the data; the maximum number of total passengers is between 70,000–80,000). Panel (d) presents a kernel density estimate (KDE) plot.

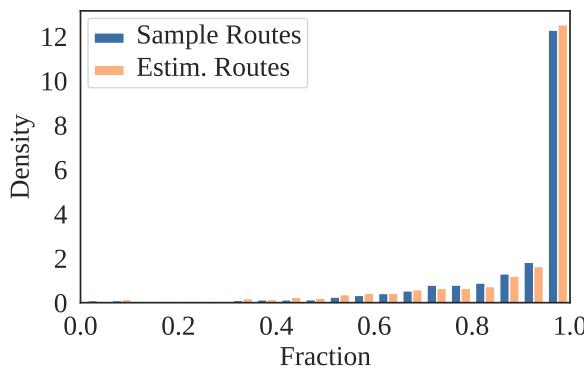

Table B.9: Estimation Sample Comparison

Characteristic	All Routes	Single Carrier Only	Estimation
Number of Nonstop Passengers	4415.0 (7164.8)	2973.4 (3018.3)	2445.2 (2441.4)
Total Number of Passengers	9808.4 (10419.0)	8041.2 (5717.5)	7014.7 (5023.8)
Number of Local Passengers	4769.4 (7357.1)	3281.8 (3202.4)	2683.2 (2503.8)
Fraction of Traffic Nonstop	89.3 (15.1)	90.1 (15.0)	89.2 (16.1)
Fraction of Traffic Non-Connecting	44.7 (23.2)	41.5 (22.1)	40.7 (20.3)

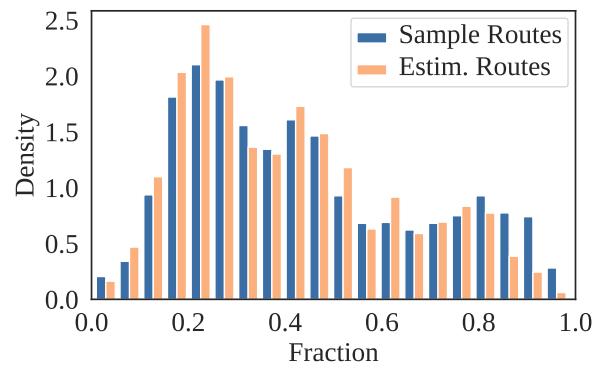

Note: The table presents statistics calculated using the 2018-2019 DB1B data across routes. Standard deviations are included in parentheses. All routes means all 470 routes in our sample; single-carrier only means the airline is the only nonstop carrier; estimation means the routes included in the estimation sample.

Figure B.18: Sample vs. Estimation Sample Route Traffic Comparison

(a) Fraction Traffic Nonstop

(b) Fraction Traffic Non-Connecting

Note: The figure shows histograms over the fraction of nonstop traffic (a) and the fraction of non-connecting traffic (b) for the selected routes using the 2018-2019 DB1B data. Sample routes (blue) denotes the 470 routes in our sample; estimation routes (orange) denotes the routes included in our estimation sample.

C Additional Descriptive Evidence

C.1 Organizational Structure Across Industries

Table C.10: Job Descriptions for Pricing Analysts

Company	Industry	Excerpts from Job Description
Alaska Airlines	Airline	<p>“The Senior Pricing Analyst analyzes changes in market conditions such as capacity, competition, schedules, and fares to develop, implement and track appropriate pricing strategies.”</p>
American Airlines	Airline	<p>“Working together, the Pricing Analysts focus on competitive analysis to determine optimal pricing across the network and create new fare products to capitalize on changes in consumer buying habits... ”</p>
Avis Budget Group	Rental Cars	<p>“Ensure correct application of pricing strategies into applicable systems and databases... Identify and examine markets, geographic regions, competitor pricing, and overall business trends in relation to pricing...Identify and test targeted promotions to align with the organizations pricing strategies”</p>
Azul Brazilian	Airline	<p>“To monitor and help pricing team to react competition pricing changes quickly in order to not lose sales...To define pricing strategies and aid pricing analysts on how to achieve the best performance of their clusters... Responsible for analyz[ing] the markets trends and guide the team to achieve the company’s goals....”</p>

Continued on next page

Table C.10: Job Descriptions for Pricing Analysts (continued)

Carnival Group	Cruises	<p>“Develops strategic cruise pricing for senior management review by analyzing booking trends associated with previous pricing actions...Researches and prepares data on competitor pricing...”</p>
Delta Airlines	Airlines	<p>“Monitor, initiate and communicate industry pricing actions including changes to fare levels, fare rules, policies, and pricing strategy execution... Proactively manage Delta’s fare structure including prices and fare rules... Identify and analyze market issues and trends, determining appropriate pricing actions, filing of actions... Synthesize high-level trends and market specific data to establish a fare structure to best segment customers and maximize revenue... Partner with ATPCO, all Global Distribution Systems, the Commercial teams, and other stakeholders to develop, support and enhance the functionality of automated pricing and distribution systems”</p>
Frontier	Airlines	<p>“Develops tactical and strategic pricing initiatives to maximize overall passenger revenue and align with company objectives. Monitors competitive pricing environment and ensures that Frontiers fares are appropriately positioned. Communicates pricing activity to Revenue Management peers and leaders.”</p>

Table C.15: Synthesized Forecasting Data Example

Variable	Value
Origin	ABC
Destination	DEF
Date	2017-10-01
Flight Number	1234
Departure Time	8:00:00
Arrival Time	10:30:00
Departure Date	2018-08-18
Equipment	DC-3
Cabin	Economy
Booking Class	N
Lowest Available Class	N
Passenger Type	Leisure
Forecasting Date	2017-10-01
Base Class Forecast	0.33236
Adjusted Class Forecast	0.31236

Note: The first column shows variables included in the actual data; values are synthesized. The base class forecast is the quantity demand prediction of charging fare N for the given origin, destination, flight number, departure date, and forecasting date. The difference between the departure date and forecasting date provide the number of days before departure. The adjusted class forecast accounts for analyst adjustments and is the final forecast used by the optimizer when allocating remaining inventory.

Note: The table includes active fares for Air France, London Heathrow (LHR) to Paris Charles de Gaulle Airport (CDG) for September 1, 2023. Fares obtained June 9, 2023 from the website ExpertFlyer.com.

C.3 Search Data Cleaning and Clickstream Patterns

The clickstream data are constructed from consumer activity on the airline’s website and mobile site. Both consumer-level and interactions-level data are collected. Consumer-level data includes browser and device information. This information can be used for bot detection, as we describe below. We use cookie information to identify users using a hashed cookie identifier, which allows us to track users across enumerated sessions unless an individual clears their current browser’s cache, switches devices, uses incognito mode, or switches browsers. If a user logs into their loyalty account, we are able to match their behavior across different cookie identifiers using their hashed airline loyalty identifier. By interactions data, we mean a set of “clicks” that are tracked, including users arriving to the website, logging into the website, searching for flights, making a purchase, etc. For this project, we only use clicks related to login, flight search, and viewing search results pages.

We use the following cleaning criteria on the raw data:

- i) We remove observations in which the departure, arrival, or return dates are mismeasured.
These values contain “N/A” in the relevant fields;
- ii) We keep activity related to one-way or round-trip travel;
- iii) We exclude observations in which the number of connections is greater than two;
- iv) We remove activity related to refunds or flight changes;
- v) We exclude sessions that are flagged as bot or automated traffic using a session quality measure included in the clickstream data. The quality score ranges from one to 100 and is provided by the web analytics service. We remove observations in which the score equals one, which is assigned to internet activity that is consistent with bot traffic.

We verify that our cleaning script generally removes observations where multiple of the following hold: (a) activity originates from other countries, (b) activity originates from a Linux operating system, (c) user computers do not indicate a monitor is being used (i.e., there is no screen resolution), and (d) activity has total time on the site measured to be in the milliseconds.

We create three data tables based on processed clickstream data. The first we call “logins.” These entries are recorded when a consumer logs into her loyalty account. Each login contains a hashed cookie identifier and device identifier. By processing all logins, we create a map of hashed consumer IDs to hashed cookie IDs. We use this mapping to investigate re-shopping (shopping for the same trip over multiple search dates) behavior.

The second data set we construct are “impressions.” These entries correspond to the information consumers see when viewing flight result pages. For this project, we use these data to augment our market size calculations that we describe below. Our cleaned impressions sample contains 143 million observations that we use to construct arrivals.

The third data set we construct are “searches.” These entries are recorded when a consumer submits a search query on the airline’s website. Table C.14 contains a synthesized search query example. Note that the impressions data also contain these key variables, but they also include flight-specific information for each flight that the consumer observes. We do not use the impression results in this project. Our cleaned search query sample contains 68 million observations that we use to construct arrivals.

Arrivals are calculated at the route, departure date, and search date level. We first check for duplicate entries at the cookie-origin-destination-departure date-return date level in both the impressions and search data. For example, if a consumer searches an itinerary, adjusts the departure date, and then searches the original itinerary again, we record two entries of search activity instead of three. With these cleaned data, we sum the following counts:

- i) Count of the total number of passengers across all unique search queries for one-way and round-trip searches where the route is the outbound leg;
- ii) Count of the total number of passengers across all unique search queries where the route is the return of a round-trip itinerary;
- iii) Count of the total number of passengers across all unique impressions for one-way and round-trip searches where the route is the outbound leg;
- iv) Count of the total number of passengers across all unique impressions where the route is the return of a round-trip itinerary.

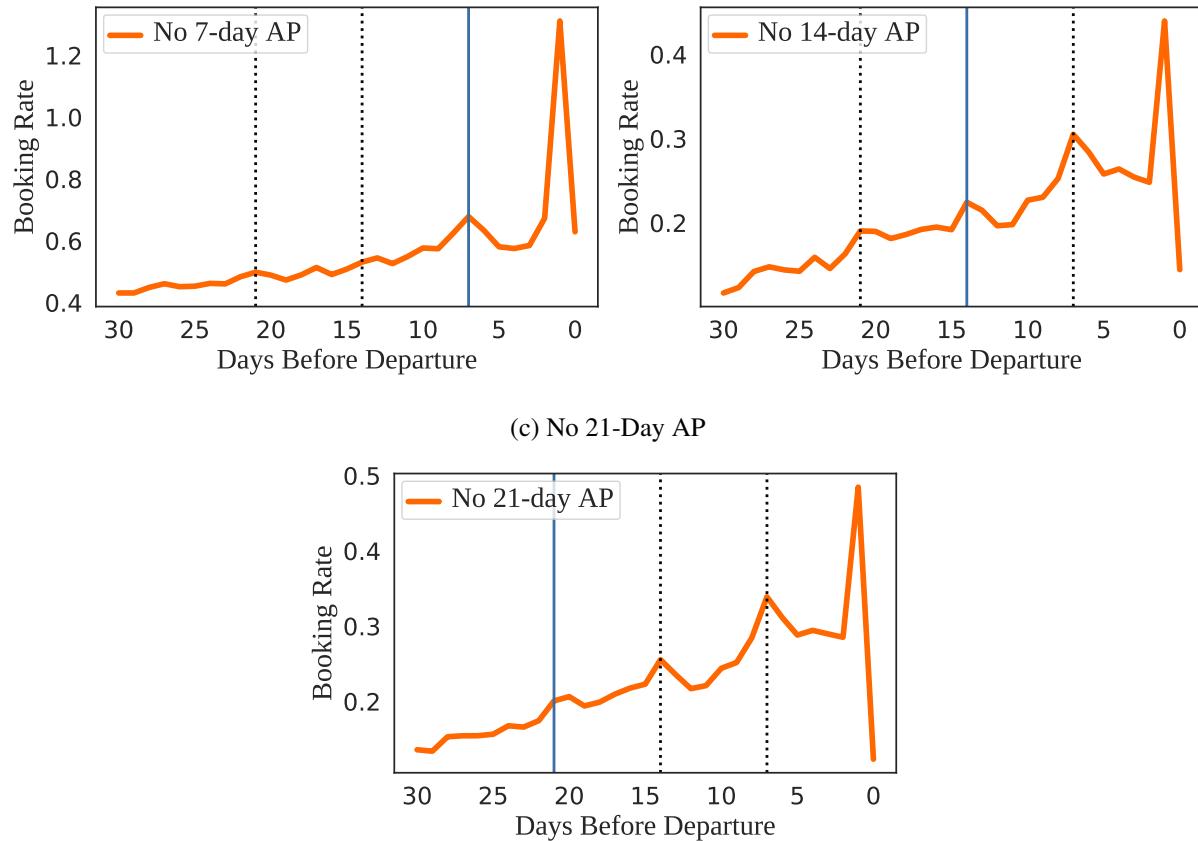

We calculate and add (iii) and (iv) to our measure of arrivals, since some consumers are redirected to the firm’s website from an internal source where the search query is not recorded. In calculating arrivals, we first verify if recorded impressions do not have corresponding searches to ensure no double-counting.

C.4 Booking Trends Around Advance Purchase Cutoff Times

There are small spikes in the booking rates across all channels when AP fares expire. This includes 7, 14, and 21 days before departure. Although this may suggest some consumers strategically time market participation, we also find support for the assumption that these days simply have higher demands. This may be due to travel websites that suggest consumers should purchase before a certain time.

We create three subsets of the data based on the absence of AP requirements. For example, there are routes in our data that never have 7-day AP fare requirements for the entire sample period. We repeat this process for routes that never have 14-day AP requirements and routes that never have 21-day AP requirements. In Figure C.19, we plot the average booking rates over days before departure for these three subsets of the data. We focus on the last 30 days before departure. The plots show that there is bunching at 7, 14, and 21 days before departure, respectively, even though these routes do not have such requirements (and thus no systematic corresponding price increases). That is, booking rates are higher, even though there is no discontinuity in fares after crossing 7, 14, and 21 days before departure, respectively. We use this evidence to motivate including time-varying fixed effects in our arrival processes. We do not model arrivals as being a function of price. Rather, we maintain the commonly used assumption that consumer choice is a function of price, conditional on arrival.

Figure C.19: Booking Rates for Routes without AP Discounts
 (a) No 7-Day AP (b) No 14-Day AP

The figure includes: (a) Average booking rate for routes without a 7-day AP discount, (b) Average booking rate for routes without a 14-day AP discount, and (c) Average booking rate for routes without a 21-day AP discount. Solid vertical lines correspond to the timing of the AP discount *not* present in each set of routes.

D Additional Demand Tables

D.1 Route-Level Demand Estimates

The following tables provide route-level demand estimates for the 140 routes included in our structural analysis.

Table D.17: Demand Results Summary Table

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of Obs.”, the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ”, the mean of the estimated posterior distribution for the arrivals process is in “A”, the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of Obs.”, the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ”, the mean of the estimated posterior distribution for the arrivals process is in “A”, the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

D.2 Demand Estimation Details

Table D.32 presents details of the prior distribution choices. Table D.33 presents the candidate distribution for the Metropolis-Hastings steps used in estimation.

Table D.32: Prior Distribution Details

Parameter	Prior Distribution	Sampling Step	Further Details
λ	Uniform density over \mathbb{R}	Metropolis-Hastings	$\lambda_{t,d} = \exp(\lambda_t + \lambda_d)$
$s(\cdot)$	Uniform(0, 1)	Metropolis-Hastings	
α_B, α_L	Log Normal(.5, .5)	Metropolis-Hastings	$\alpha_L > \alpha_B$
ψ	Uniform density over \mathbb{R}	Metropolis-Hastings	$\gamma_t = \text{Logit}(G(t)'\psi)$
β	Standard Normal(0, .1I)	Gibbs	
η_k	Standard Normal(0, .1I)	Gibbs	
Σ_k	Inverse Wishart($I, 3$)	Gibbs	

Note: All parameters and estimation are route-specific.

Table D.33: M-H Candidate Distribution Details

Parameter	Sampling Step	Candidate Dist.
λ	Metropolis-Hastings	Normal
$s(\cdot)$	Metropolis-Hastings	Normal
α_B, α_L	Metropolis-Hastings	Normal
$\gamma_t = \text{Logit}(G(t)'\psi)$	Metropolis-Hastings	Normal

Note: All parameters and estimation are route-specific.

D.3 Alternative Instrument Demand Results

We check the robustness of our demand results by considering additional instrument specifications. Here, we consider two alternative instruments. We re-estimate demand for all 140 routes included in our estimation sample.

First, we estimate demand using solely the onward connecting traffic instrument. Second, we use solely the opportunity cost instrument. Tables summarizing the demand results, analogous to the presentation of the baseline specification in Table II, appear in Table D.34 and Table D.35, respectively.

We find that our demand results are robust across instrument choice. Parameter estimates are similar across specifications, and average demand elasticities range between -1.1 to -1.2 .

across specifications. Figure D.20 plots price coefficients and route-level elasticities across instrument specifications. Each point is a pair of route estimates under a different alternative instrument (y axis) compared to the baseline estimate (x axis).

Figure D.20: Alternative Instrument Parameter Estimates

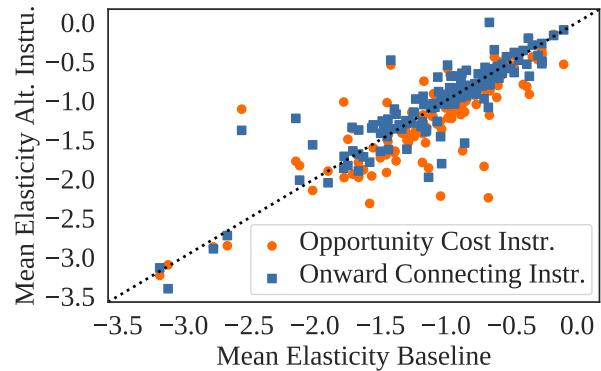

(a) Leisure Price Sensitivity

(b) Business Price Sensitivity

(c) Route-Level Elasticities

Note: Each observation is a route-level posterior mean under alternative instrument sets. The figure shows: (a) a comparison of the leisure price sensitivity coefficients across instrument specifications, (b) a comparison of the business price sensitivity coefficients across instrument specifications, and (c) a comparison of the mean route-level demand elasticity across instrument specifications.

D.4 The Impact of the Scaling Factor on Demand Estimates

We consider alternative specifications on our scaling factor ζ in order to understand how changes in imputed market size affect our demand estimates. We investigate two potential concerns: (i) that we are understating true arrivals if many individuals shop on travel websites, and (ii) our scaling factor may underestimate the presence of price-sensitive consumers who may primarily shop for tickets via online travel agencies early on. Therefore, we conduct three sets of robustness exercises. First, we multiply our arrival rates by an additional 50% within estimation and re-estimate demand for all 140 routes. Table D.36 shows a summary of our findings—parameter estimates are quantatively similar to our baseline estimates. Figure D.21 compares price coefficients and demand elasticities. Each point is a route.

Second, we multiply our estimated arrival rates by 1.5, 2, 2.5, ..., 5 within estimation for a single route. This is on top of the scaling factors included in estimation. Third, we repeat this exercise, but only consider the additional scaling for greater than 30 days before departure. Within 30 days before departure, we set this additional scaling factor equal to one, i.e., we do not adjust it from our baseline arrival adjustment.

We apply the 16 robustness exercises to an example route (“Route 1”). This route’s original demand elasticities are close to the average found across all routes, -1.2 , compared to -1.1 across all routes. In Table D.37, we provide demand estimates for the first set of demand robustness specifications. The first column denotes the route’s baseline demand estimates. The following columns provide demand estimates under the additional scaling factors that are applied for all days before departure. Similarly, Table D.38 provides demand estimates for “Route 1” for the additional eight demand specifications, where each column denotes the scaling factor that affects arrival rates early on (greater than 30 days before departure). The first column again repeats the original demand estimates.

Across all sixteen additional specifications, we find that demand elasticities are stable, with averages between -1.2 and -1.0 . Two specifications result in average demand elasticities closer to -0.9 . These occur when market sizes are scaled up by over 350% compared to our original estimates. Critically, we confirm that under smaller additional scaling factors, such as $1.5\times$, where arrival rates are scaled up by an additional 50%, demand elasticities and estimated

parameter values hardly change. The general pattern we find is that as the additional scaling factor increases, price sensitivities generally increase. For the scaling parameters that affect arrivals greater than 30 days before departure, there is a greater effect on the leisure consumer price sensitivity.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q,” our model’s prediction of the average total number of purchases is in “Model Q,” and the estimated mean own-price elasticities are reported in the row labeled “Elas.” We also report the 5th and 95th percentiles in parentheses. Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

D.5 Demand Estimates Imposing Supply-Side Conditions

Table D.39 compares demand estimates assuming observed prices are the result of the firm solving a dynamic programming problem as a single entity. We use the model of Williams (2022) for demonstration purposes. The dynamic program is given by

$$V_t(C_t, \omega_t) = \max_{p \in \text{Fares}(t)} \left(p_t \cdot \mathbb{E}_t [q_t(p_t; C_t)] + \omega_{tp} + \int_{\omega_{t+1}, C_{t+1} | \omega_t, p, C_t} V_{t+1}(C_{t+1}, \omega_{t+1}) dH_t(\omega_{t+1}, C_{t+1} | \omega_t, p, C_t) \right),$$

where $V_t(C_t, \omega_t)$ is the value function given the state (t, C_t, ω_t) , $\omega_t \in \mathbb{R}^{A(t)}$ are assumed to be IID Type-1 Extreme Value (T1EV) unobservables, with scale parameter $\sigma > 0$, $\text{Fares}(t)$ are the pricing department's fare decisions for period t , and $\mathbb{E}_t [q_t(p_t; C_t)]$ is expected demand. We assume conditional independence is satisfied and therefore, $h_t(\omega_{t+1}, C_{t+1} | \omega_t, p_t, C_t) = g(\omega_{t+1})f_t(C_{t+1} | p_t, C_t)$. The capacity transitions $f_t(\cdot)$ are also based on the censored Poisson distributions of demand and are equal to $C_{t+1} = C_t - \min \{\tilde{q}_t, C_t\}$, where \tilde{q}_t is the realized demand draw. The firm faces two boundary conditions: (i) unsold seats are scrapped and (ii) it cannot sell any additional seats if $C_t = 0$. For this route, almost all departures have a single flight per day. When there is more than one flight a day, we assume they are priced independently. Finally, we use $\lambda_{t,d,r}^B$ and $\tilde{\lambda}_{t,d,r}^L$ as inputs and therefore, do not re-estimate these parameters.

With these assumptions, the conditional value function is equal to

$$EV_t(p_t, C_t) = \int_{C_{t+1}} \left[\sigma \ln \left(\sum_{p_{t+1} \in \text{Fares}(t)} \exp \left(\frac{p_{t+1} \cdot \mathbb{E}_{t+1} [q_{t+1}(p_{t+1}; C_{t+1})] + EV_{t+1}(p_{t+1}, C_{t+1})}{\sigma} \right) \right) \right] \\ \times f_t(C_{t+1} | C_t, p_t) + \sigma \phi,$$

where ϕ is Euler's constant. The probability the firm chooses price p_t is equal to

$$CCP_t(p_t; C_t) = \frac{\exp \{(p_t \cdot \mathbb{E}_t [q_t(p_t; C_t)] + EV_t(p_t, C_t)) / \sigma\}}{\sum_{p'_t \in \text{Fares}(t)} \exp \{(p'_t \cdot \mathbb{E}_t [q_t(p'_t; C_t)] + EV_t(p'_t, C_t)) / \sigma\}}.$$

Finally, this allows us to obtain the following log-likelihood for the sample

$$\max_{\alpha, \beta, \sigma} \sum_F \sum_T \log (CCP_t(p_t; C_t)) + \log (f_t(C_{t+1}|C_t, p_t)).$$

Table D.39 presents demand estimates for “Route 1” using our demand model followed by this approach. We find that expected consumer surplus using our demand estimates is \$87. Imposing optimality conditions in demand estimation results in expected consumer surplus equal to \$18.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of Obs,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of Obs,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.

Note: For the “parameter” rows we report the mean and standard deviation (in parentheses) of the estimated posterior distributions of the preference parameters excluding the week and time of departure (ToD) fixed effects. For the “summary” rows, we provide additional information about the estimates and underlying data. The fraction of observations in the data that have no purchases is reported in the row labeled “Percent. of 0s,” the r-squared of a regression of prices on the controls and instruments is in “First stage R^2 ,” the mean of the estimated posterior distribution for the arrivals process is in “A,” the average total number of purchases observed in the data is in “Emp. Q” with the 5th and 95th percentile of purchases in parentheses, our model’s prediction of the average total number of purchases is in “Model Q” with the 5th and 95th percentile of predicted purchases in parentheses, and the estimated mean own-price elasticities are reported in the row labeled “Elas.” Finally, we report the number of flights, departure days, and total number of observations used in estimation. All parameters and summary values are route-specific.
