Automatic Tax Filing: Simulating a Pre-Populated Form 1040 Lucas Goodman, Katherine Lim, Bruce Sacerdote, and Andrew Whitten NBER Working Paper No. 30008 April 2022 JEL No. H0,H2,H24,I3

ABSTRACT

Each year Americans spend over two billion hours and \$30 billion preparing individual tax returns, and these filing costs are regressive. To lower and redistribute the filing burden, some commentators have proposed having the IRS pre-populate tax returns for individuals. We evaluate this hypothetical policy using a large, nationally representative sample of returns filed for the tax year 2019. Our baseline results indicate that between 62 and 73 million returns (41 to 48 percent of all returns) could be accurately pre-populated using only current-year information returns and the prior-year return. Accuracy rates decline with income and are higher for taxpayers who have fewer dependents or are unmarried. We also examine 2019 non-filers, finding that pre-populated returns tentatively indicate \$9.0 billion in refunds due to 12 million (22 percent) of them.

The direct costs of individual income tax compliance are large and growing. Marcuss et al. (2013) estimate that the average filer spends \$200 and 12.5 hours to file an individual income tax return. This adds up to over two billion hours and \$30 billion in tax preparation fees, software costs, and filing fees each year. To make the process more efficient, and to redistribute this burden more progressively, some commentators have proposed having the Internal Revenue Service (IRS) pre-populate returns on behalf of individual taxpayers. After all, the IRS already receives information returns for many of the key income sources reported on tax returns, including for wages (Form W-2); unemployment compensation (Form 1099-G); interest, dividends and capital gains (Forms 1099-B and 1099-DIV); non-employee compensation (Form 1099-MISC or 1099-NEC); and income from partnerships and S corporations (Forms 1065 and 1120S, Schedule K-1). Moreover, the IRS could infer filing status and dependents based on prior year returns. Pre-population may have the additional benefit of encouraging non-filers to claim refunds (e.g. from unclaimed EITC or Child Tax Credits) or to meet their filing obligations.

In this paper, we explore the degree to which such pre-populated returns would have been "successful" for tax year 2019. Broadly, we take two approaches to measure success. In our first approach, we check for tax situations that would result in an inaccurate pre-populated return, such as reporting a nontrivial amount of income, deduction, or credit on the 2019 filed tax return that the IRS does not observe on an information return. A return without any of these failure situations is deemed a success under this approach, which we refer to as the "upper bound" approach because it will tend to overstate the success rate due to our inability to enumerate and measure *all* potential failure situations.

In our second approach, we simulate a pre-populated 2019 Form 1040 line by line, using only the taxpayer's 2019 information returns and their 2018 Form 1040 if they filed one. We calculate tax liability using NBER TAXSIM (Feenberg and Coutts, 1993), generally assuming that the taxpayer has the same filing status and dependents as the prior year. Under this approach, a pre-populated return is deemed successful if its calculated tax liability is approximately equal to the tax liability actually reported on the 2019 tax return (within a tolerance threshold of \$100 in our baseline results). We refer to this as a "lower bound" approach because it will tend to understate the success rate relative to a richer tax calculator.¹

Using our baseline tolerance thresholds, our lower and upper bound procedures are successful for 62 and 73 million returns (41 and 48 percent of filers), respectively. In about two-thirds of the cases where the lower bound approach is inaccurate, the pre-populated liability is higher than the reported liability, with a median gap of \$4,200. For both the lower and upper bounds, we find that success rates are decreasing in income, from 60-80 percent in the bottom income decile to 10-30 percent in the top income decile. The higher rates of failure for higher-income taxpayers are largely driven by increasing rates of itemized deductions, which cause a divergence between pre-populated and actual returns. Pre-population is particularly successful for taxpayers who are single, young, and lack dependents. Suggestive of the potential benefits to pre-population, among those taxpayers who would have an accurately pre-populated return, 43 to 44 percent used a paid preparer when filing.

Pre-population can still yield significant time savings even for taxpayers for whom the IRS cannot fully complete their return. Among the 52 to 59 percent of taxpayers with inaccurately pre-populated returns, the majority would need to make only one change or complete one additional schedule (e.g., reporting self-employment income and deductions on Schedule C — and attaching any schedules required

¹We use the term "bound" loosely. Our approaches do not yield true mathematical upper or lower bounds, as explained further in Section II.

for that Schedule C — which would be the most common edit required).

Next, we consider refinements of the pre-population procedure in which the IRS pre-populates returns for certain subsets of taxpayers. In the narrowest subset – single taxpayers with no dependents, with only wage income, and with only deductions or credits that are observed by the IRS² – we estimate that around 80 percent of these returns could be successfully pre-populated. The imperfect success rate for this group is partly due to the mismatch rate between wages reported on information returns vs. tax returns. Among wage earners, we accurately pre-populate this line of the Form 1040 only 90 percent of the time.

Beyond the time and cost savings to current filers, another potential benefit of pre-populated returns is that they could be created for current non-filers, potentially nudging them into claiming refunds or paying taxes due. For tax year 2019, we find 46.3 million individuals who received an information return, did not file a tax return, and did not appear not to have a filing obligation based on income on their information returns.³ Our pre-populated returns indicate that 17 percent (8.0 million) of these individuals are entitled to a refund, with an average potential refund of \$387. We additionally identify 8.8 million non-filers who appear to have a filing obligation based on their information returns. Among this population, 55 percent (4.9 million) appear to have a balance due. Guyton et al. (2016) find that non-filers are more likely to file after receiving a reminder, and pre-populated returns may provide this reminder.

Our findings extend the existing work on pre-populated returns in the U.S. – which we describe in the next section – by using individual-level administrative data to calculate success rates along a number of taxpayer characteristics. We also update the literature by using data from after the 2017 tax reform, which (among other changes) reduced the prevalence of itemized deductions substantially. Moreover, our sample size allows us to focus on specific subgroups of taxpayers as well as non-filers. Our detailed results can inform the design of a pre-population program for some or all U.S. taxpayers.

To be sure, substantial challenges would arise in any implementation of pre-populated returns. For one, there is the question of timing. Either providers of information returns – such as employers and financial institutions – would need to submit information returns earlier than they currently do, or the deadline for individual returns would have to be delayed. Additionally, a pre-populated return may function as a nudge toward accepting the pre-populated liability unmodified, likely changing the distribution of taxes paid. To the extent that this nudge has an effect and these pre-populated liabilities differ from "true" liabilities as legislated by Congress, various equity and efficiency policy aims could be undermined. While we abstract from these issues in this paper, we stress that policymakers must take them into account when deciding whether, and how, to implement a pre-populated return program.

I Background

Pre-populated tax returns are not a new idea. Over 45 countries at least partially pre-fill their personal income tax returns (OECD, 2021), while tax agency reconciliation systems operate successfully in a number of countries. In the U.S., more limited programs in California and Colorado have been piloted in previous years (U.S. Department of the Treasury, 2003; Fichtner, Gale and Trinca, 2019). Informed

²Unobserved items include itemized deductions; moving expenses; educator expenses; self-employment health insurance; and credits other than the Earned Income Tax Credit, Child Tax Credit, American Opportunity Tax Credit, or the credit for excess Social Security tax.

³For this analysis, we include all information returns with U.S. addresses, including but not limited to Form W-2, the Form 1099 series, and the Form 1095 series.

by these experiences, academics and practitioners have analyzed the possibility of pre-populating tax returns in the U.S. (U.S. Department of the Treasury, 2003; Goolsbee, 2006; Cordes and Holen, 2010; Fichtner, Gale and Trinca, 2019). All of these reports have noted that certain features of the U.S. tax system make universally automated returns infeasible. Given the extant Internal Revenue Code and information reporting requirements, some taxpayers will always have to adjust their returns. Countries currently using exact withholding or tax agency reconciliation systems generally have individual-level taxation (i.e., tax schedules independent of family structure) where most taxpayers face the same marginal tax rate with few deductions, allowances, and credits.

In the U.S. context, previous work has relied on cross-sectional information on filers for a single year (Gale and Holtzblatt, 1997; U.S. Department of the Treasury, 2003; Goolsbee, 2006). Goolsbee (2006) proposes a Simple Return and uses the IRS Individual Public Use File to calculate the share of taxpayers in various cells starting from the most restrictive and therefore easiest to serve. This group consists of single taxpayers with no dependents, wage income only, no Earned Income Tax Credit (EITC), no itemized deductions, and no additional credits, representing only seven percent of all taxpayers. Under more relaxed constraints, Goolsbee (2006) finds that up to 40 percent of taxpayers could be served with the Simple Return.

II Analytical Approach and Data

Throughout this paper, we consider variations of the following simple procedure, where in our case t=2019. The IRS begins by observing several items from a t-1 tax return for filer i: the identity and age of i's dependents, i's filing status, and the identity of both the primary and secondary filer (if any). The IRS then prepares a pre-populated return for year t assuming that filing status, dependent status, and the identity of the primary and secondary filers remain constant – except that we assume that a dependent who reaches age 24 in t is no longer a dependent in t. In preparing the year t return, all income calculations are exclusively derived from year t information returns. Moreover, we make the strong assumption that all information returns are made available to the IRS prior to the construction of the pre-populated return.

To evaluate the success of this hypothetical production of pre-populated returns, we use a stratified random sample of 344,400 individual income tax returns for 2019 constructed by the Statistics of Income Division of the IRS. These data include information from nearly every line or box on Form 1040 and its schedules. The sampling rate is increasing in income, with the highest-income taxpayers sampled with certainty. In all specifications, we use sampling weights to make the sample representative of the full tax-filing population (152 million tax units). We treat filed tax returns as the "truth". That is, we gauge the success of pre-populated returns by how closely they match these actually-filed returns. This approach is conservative, as we misclassify returns as "unsuccessful" when taxpayer-reported returns contain errors and the pre-populated return is, in fact, accurate.

We merge the sampled 2019 tax returns with their associated administrative data in 2018 and 2019. In particular, we measure income using 2019 information returns⁶ and we use the 2018 Form 1040 to

 $^{^4}$ We also assume the IRS observes on the t-1 tax return the amount of any capital loss carryforward and any amount of state income tax deducted, the latter of which is necessary to compute taxable refunds of state income tax.

⁵The rules for claiming dependents are substantially stricter for dependents above age 24.

⁶We use income from the following information returns: Form W-2, Form W-2G, Form 1099-DIV, Form 1099-INT, Form 1099-G, Form 1099-R, Form 1099-SSA, Form 1099-B, Form 1099-MISC, Form 1065 (Schedule K-1), and Form 1120S (Schedule K-1).

identify their 2018 dependents, filing status, and the identity of the 2018 primary and secondary filer.⁷

We use two methods to gauge the accuracy of pre-populated returns. First, we identify situations where the pre-populated return is almost certainly inaccurate – we refer to these as "failure situations". If a taxpayer does not have any of these failure situations, their return is deemed a "success." Because we cannot enumerate and measure all possible failure situations, we refer to this approach as an estimated "upper bound." These failure situations fall into three sets. The first set includes those situations where the tax unit composition appears to have changed – e.g., a baby is born, or the taxpayer married or divorced. The second set includes situations where the taxpayer claims a tax credit or deduction that is not covered by information returns. This includes essentially everyone who itemizes their deductions, as there is no information return for state property taxes or charitable contributions, which (together) are nearly universal among itemizers. The third set includes situations where the taxpayer has income that either is unreported on information returns or does not match (subject to a tolerance threshold) the income based on information returns. For example, a failure situation occurs when Schedule C (sole proprietorship) net income does not match non-employee compensation from Form 1099-MISC, which can occur if a taxpayer has other self-employment income or has expenses to deduct. In total, we identify 22 failure situations.

Second, we provide a more direct test: we compare the taxpayer's self-reported tax liability to her simulated pre-populated return liability calculated using NBER TAXSIM (Feenberg and Coutts, 1993). If the two amounts are within a tolerance threshold, then we deem the procedure successful. TAXSIM captures the most important features of the federal income tax system, including the EITC, the CTC, the alternative minimum tax, and the qualified business income deduction, among other features. However, the calculator has a limited set of input variables and therefore cannot accommodate some of the data derived from information returns, including the saver's credit, the deduction for student loan interest, and the reconciliation of premium tax credits received under the Affordable Care Act. In addition, TAXSIM imposes some constraints upon its input data that simplify, and thus imperfectly reflect, the tax code. Therefore a richer calculator may accurately pre-populate additional returns. For this reason, we refer to this exercise as a "lower bound".

We note that these "bounds" are not strict upper and lower bounds in the mathematical sense. For example, a tax unit may have a failure situation that affects its income but not its tax liability if its taxable income would have been zero regardless. This would result in a lower bound success but an upper bound failure. Additionally, a given return may have multiple failure situations that happen to have perfectly offsetting effects on liability, again creating a lower bound success but an upper bound failure. These situations are more common for certain groups of taxpayers, which can result in an estimated "upper bound" success rate that falls below the "lower bound", as indeed occurs for some income groups in Figure 1 (described later).

⁷See Appendix A.1.3 for details on our assumptions regarding 2019 dependents.

⁸We calculate the earned income tax credit (EITC) and child tax credit (CTC) automatically, based on assumed dependent and eligibility status from 2018 and calculated income. The presence of EITC or CTC is not a failure situation.

⁹In Appendix A.2, we describe all of the failure situations that we consider.

¹⁰For this purpose, we conform the definition of "tax liability" to match the TAXSIM definition. Tax liability is defined as "total tax" (Line 16 of 2019 Form 1040) less the sum of self-employment tax and all refundable credits. For our purposes, "refundable credits" do not include direct payments (e.g., withholding or estimated tax payments) or excess Social Security tax withheld. This concept of tax liability does not include payroll (FICA) tax, though it does include the 0.9% Additional Medicare Tax.

¹¹To protect taxpayer privacy, we use an internal version of TAXSIM; however, the calculator used is identical to the public version available here: http://www.nber.org/taxsim/.

III Results

Using our preferred tolerance levels, our baseline results are that 41 and 48 percent of pre-populated returns are successful under our lower and upper bound approaches, respectively, as shown in Table 1. For the lower bound approach, we consider returns with differences between pre-populated tax liability and taxpayer-reported liability of \$100 or less to be a success. For the upper bound approach, we similarly allow differences between pre-populated and taxpayer-reported tax credits of up to \$100, while for income and deduction amounts we allow differences of up to \$500. Implicitly this assumes a 20 percent effective tax rate, such that a \$500 adjustment to income would change tax liability by \$100. The probability of success varies as we alter the error tolerances, but within a wide range of tolerances we find that between 33 and 60 percent of taxpayers have an accurate pre-populated return.

In Table 1, we also consider an alternative pre-population regime wherein the IRS first solicits accurate information about current year t filing status and dependents, then pre-populates a return using income from information returns. Perfectly implemented, this exercise eliminates dependent and filling status errors, which improves the success rate of pre-population by around five percentage points (7.6 million taxpayers) using our preferred tolerance thresholds. We note, though, that procuring this additional information may be costly for the IRS and taxpayers alike.

In Figure 1 we show that both our upper and lower bound approaches have higher rates of success for low- to moderate-income taxpayers, classified by the AGI reported on the tax return. In the graph, each data point represents an income ventile (conditional on positive AGI) and therefore each represents the same number of taxpayers. For taxpayers in the bottom three ventiles, with average incomes between \$0 and \$10,000, success rates are between 61 and 80 percent. Success rates remain high well into the middle part of the income distribution. For example, taxpayers earning around \$60,000 (the thirteenth ventile) have success rates between 34 and 51 percent. The graph illustrates the looseness of our "upper bound" and "lower bound" terminology, as the upper bound lies below the lower bound for the bottom four income ventiles. This is because many of these taxpayers have taxable income of \$0, meaning that the presence of a failure situation need not imply an incorrect tax liability calculation.

Under our upper bound approach, the most common failure scenario overall is the presence of Schedule C income that doesn't match Form 1099-MISC non-employee compensation, which occurs for 16 percent of taxpayers. Next, around 11 percent of taxpayers itemize deductions. Taxpayers with these situations would need to file an additional schedule (C or A, respectively). In contrast, the next most common failure scenario is a nontrivial mismatch between Form W-2 and reported wage income. ¹² The nine percent of taxpayers with this issue may only need to edit one line of the tax return. ¹³

Conditional on reporting wages on their tax return, we find that the wage line is pre-populated accurately 90% of the time. Conditional match rates are similar for taxable interest and qualified dividends. Conditional match rates are somewhat lower for pensions (81%) and are much lower for capital gains (44%) and Schedule 1 income (23%), a category that includes Schedule C (sole proprietor) income, Schedule E income (rents, royalties, S corporation income, and partnership income), unemployment compensation, and other less common income types.¹⁴

Table 2 provides summary statistics on the taxpayers for whom pre-population is successful under the two approaches. On average, taxpayers for whom pre-population works are several years younger

¹²We report the prevalence of the full set of 22 failure situations in Appendix Table A2.

¹³In some circumstances, such as unreported tip income, additional forms are required.

¹⁴See Appendix Table A3 for detail on the success rate for pre-populating key lines of the 2019 Form-1040 using our lower bound approach.

and 20 to 27 percentage points less likely to be married than taxpayers for whom the pre-population exercise is unsuccessful. As expected, taxpayers who have successful pre-populated returns are less likely to have dependents. Consistent with Figure 1, the group of taxpayers for whom pre-populated returns is successful have lower average income. In the upper bound approach, the successful group have average incomes of \$47,200 versus \$104,000 in the unsuccessful group. For the unsuccessful group under the lower bound approach, we separately consider those where pre-populated tax liability is too high (column 4) and those where it is too low (column 5). The group for whom the pre-populated liability is too low are particularly high income, with average incomes of \$150,300.

The primary benefit of a pre-populated tax return is that it may reduce the costs of tax filing. Table 2 illustrates this in columns (1) and (3), as we see that 43 or 44 percent of taxpayers for whom pre-populated returns are accurate currently use paid preparers. Moreover, among individuals for whom pre-populated returns are inaccurate, the median number of failure situations is one. That is, most individuals who would need to modify their pre-populated returns would only need to edit one line or schedule (e.g., filling out a Schedule C – and any other schedules required to be attached to that Schedule C – which would be the most common edit required). For this group the pre-populated return may substantially reduce the costs of tax filing as well.

Inaccurately pre-populated returns could introduce new tax administration challenges. Taxpayers with overestimated liability would have a strong incentive to correct their return, but those with underestimated liability may be less likely to make the required adjustments. A pre-populated return might make salient to taxpayers that the IRS is not aware of certain components of their income, potentially reducing voluntary compliance. To bound the scope of this problem, we estimate that if taxpayers made only favorable adjustments to pre-populated returns (i.e., they paid the smaller of their actually-reported tax liability or their pre-populated liability), income tax revenue would fall by 18 percent, roughly doubling the current tax gap.

On the other hand, pre-populated returns could also reduce the tax gap to the extent that they reduce misreporting on lines covered by information returns (and to the extent that such misreporting is not already recovered through post-return enforcement). In our analysis, we have treated the filed return as the "truth", with mismatches between information returns and the tax return reflecting the unique circumstances of the taxpayer which we do not observe. However, it is well-known that income misreporting on Form 1040 is substantial (Internal Revenue Service Research Applied Analytics and Statistics, 2019; U.S. Department of the Treasury, 2021). While most of this misreporting occurs on lines that are not covered by information returns – such as Schedule C income and rental income – others have found evidence consistent with strategic misreporting on lines covered by information returns as well (Mortenson and Whitten, 2020; Ramnath and Tong, 2017). Pre-populated returns could, in principle, improve compliance along this margin (Fochmann, Müller and Overesch, 2018).

Additionally, this insight reveals that our estimated accuracy rates – relative to returns filed in the absence of misreporting – may be biased downwards. That is, some mismatches on information-return covered lines, such as wages, dividends, interest, and pensions, may be attributable to taxpayer error. We can bound the effect of such misreporting by repeating our upper bound analysis but removing from the set of failure conditions any mismatches on the wages, interest, dividends, or pension/IRA lines. This raises our upper bound success rate from 48 to 56 percent. This eight percentage point jump inevitably overstates the role of taxpayer misreporting, though, since some mismatches reflect errors on the part of the information return issuer or have other legitimate explanations.

III.A Success Rates by Tax Unit Composition and Types of Income

Following the approach of Goolsbee (2006), we now analyze the success of pre-population starting with a subset of taxpayers with simple tax situations and then gradually broadening the target population. These nested subsets can inform policymakers considering more limited approaches to implementing pre-population. We start with the narrowest set of taxpayers: those who are single, with no dependents, whose only income source is wages, whose income is under \$100,000, and who have no unobserved credits or deductions. Around one-fifth of 2019 filers satisfy these restrictions, and of these, we find that between 78 and 82 percent of pre-populated returns would be successful (Table 3). It is noteworthy that success rates are substantially less than one even for such simple situations. The most common reason, under the upper bound approach, is a mismatch between Form W-2 and taxpayer-reported wages, which occurs in 70 percent of failures within the narrowest subset.

When we expand the subset of taxpayers analyzed to include married couples with dependents, this increases the number of eligible tax units by 50 percent, but the success rates fall to a range of 67 to 74 percent, as indicated in columns (2) and (3). Columns (4) and (5) describe the success rates among the people *added* in each row. That is, among tax units who are included in row 2 but not row 1, we see a success rates of 53 to 54 percent. The relatively low success rate in this group is driven largely by transitions in filing status (including from non-filing). Among those included in row 2 but not row 1 with an upper bound failure situation, 65 percent have a mismatch between this year's filing status and last year's filing status.

When we allow pre-populated returns to have additional sources of income that are at least partially covered by information returns in rows 4 through 8, the share of eligible tax units increases by 17 percentage points without a meaningful effect on success rates. In row 9, we add higher-income taxpayers, whose success rates are somewhat lower. In row 10, we allow all income types, increasing coverage by 17 percentage points. However, as expected, the marginal success rates for this group are quite low: 23 and 19 percent, respectively, under our lower and upper bound approaches. Moving to the full set of taxpayers in row 11, we recover our baseline results, with the success rate ranging from 41 to 48 percent. ¹⁶

One limitation of this exercise is that it does not inform a procedure that could be easily implemented because the IRS would not know which categories taxpayers fall under when pre-populating returns. A more readily implemented procedure would define taxpayer subsets based on the information from the prior year's (i.e., 2018) return. Under this alternative procedure, 17 percent of taxpayers would be included in the narrowest subset and 48 percent would be included in rows 1 through 8. Success rates would be somewhat lower: 69 to 77 percent in the narrowest subset and 61 to 68 percent including all of rows 1 through 8. The reduced success rates reflect the additional source of error caused by year-to-year changes. For instance, some taxpayers with only wages in 2018 might have self-employment income in 2019.

¹⁵This last restriction eliminates people who itemize deductions, who claim above-the-line deductions for moving expenses, educator expenses, or health insurance for self-employed persons, or who claim any credit other than the EITC, CTC, American Opportunity Tax Credit, or credit for excess Social Security tax.

¹⁶By construction, upper-bound marginal success rates in rows 10 and 11 are positive only when items are smaller than our tolerance thresholds.

¹⁷Appendix Table A4 replicates Table 3 for this alternative.

III.B Non-filers

One potential benefit of pre-populated returns is that it could encourage individuals who otherwise would not file to do so. This could help low-income taxpayers access refunds either through eligibility for the EITC, the CTC, or from tax withholding. It could also encourage compliance among non-filers with a filing obligation.

We examine results for a subset of non-filers in Table 4. The table is based on a 0.1% random sample of 2019 non-filers who would have received a pre-populated return under our baseline policy simulation. These are individuals between the ages of 18 and 105 who (i) appear on a 2019 information return with an address in the 50 states or the District of Columbia, and (ii) did not file a tax return as a primary or secondary filer for 2019 (as of our March 2022 data retrieval). ¹⁸

We separate our analysis by those who do and do not appear to have a legal requirement to file a tax return.¹⁹ Our sample, appropriately weighted, indicates that 46.3 million non-filers who receive information returns are not required to file. On average, these non-filers had only \$37 in taxes withheld. Seventeen percent (8.0 million) have a potential refund, and conditional on having a refund the average amount is \$387. This is consistent with evidence that, for many non-filers, the time and financial costs of filing exceed the benefits (Erard and Ho, 2001). However, a pre-populated return could help eliminate some of these barriers to claiming a refund.

One reason why potential refunds are low for these non-filers is that only two percent claimed dependents on the prior-year return. Thus for the vast majority, pre-populated returns would not include child tax benefits such as the CTC and any EITC amounts would be small under 2019 law. Nonetheless, for around one percent of these non-filers (342,000 taxpayers), pre-populated returns may increase child EITC and CTC take-up. One might expect that this number would be substantially higher if we imagine a pre-population regime wherein the IRS first solicits information about dependents and then pre-populates returns. In fact, during the COVID-19 pandemic, the IRS solicited information on dependents from non-filers for the purpose of distributing Economic Impact Payments in 2020 and 2021 as well as the 2021 advanceable CTC. In row 7, we make use of this information by assigning dependents claimed via either of these non-filer tools to 2019 non-filers. When we do so, the number of non-filers without a filing obligation who are owed child EITC or CTC increases by only 24,000. Many more of our sampled non-filers without a filing obligation – eight percent – appear eligible for the childless EITC, consistent with Guyton et al. (2016). If pre-populated returns provide a reminder to file or lower filing costs, they may increase EITC take-up.

We also estimate that 8.8 million non-filers are failing to meet a legal filing obligation. The majority (55 percent) appear to have a balance due. Reflecting the general skew in income tax liability, the mean balance due among those who owe is \$5,077, with a median of \$1,500. We stress that this calculation uses information returns only; these taxpayers may have deductions that we do not observe that more than fully offset their income. Additionally, these taxpayers may have filed a return but it has yet to be processed into our data source.

¹⁸While the filing deadline for tax year 2019 has passed, taxpayers sometimes file returns many years late. The COVID-19 pandemic may have exacerbated this for tax year 2019. We inevitably misclassify some of these very late filers as "non-filers". We exclude individuals who filed jointly in 2018 if their spouse filed a 2019 return. We stress that this is not the full population of non-filers, as it excludes individuals who do not receive any information return.

¹⁹Our proxy for the filing obligation is an indicator for whether the individual's pre-populated AGI calculation exceeds the standard deduction of \$12,200 (\$13,850 for those age 65 or older). Our estimate of non-filers with an obligation to file is consistent with Erard et al. (2014).

²⁰We additionally require that those dependents are not claimed by someone else in 2019.

IV Discussion and Conclusion

Our results suggest that pre-populated returns would be accurate for a substantial share of U.S. tax-payers. With our preferred set of tolerance thresholds, we estimate that between 41 and 48 percent of taxpayers could be sent an accurate pre-populated return. Success rates are much higher for low-and moderate-income taxpayers and those who do not have unobserved deductions or self-employment income. Furthermore, most taxpayers could benefit from a pre-populated system by receiving a return with a large number of lines correctly pre-populated as most inaccurate returns have precisely one aspect (i.e., one line or one schedule) of the return that requires editing. Success rates for some lines on the Form 1040 are quite high. We calculate wages, taxable interest, and taxable dividends correctly over 90 percent of the time. Non-filers and taxpayers that fail to take up the EITC or CTC could see significant benefits (Plueger, 2009; Guyton et al., 2016). We estimate that there are 7.2 million non-filers who are not required to file yet are owed refunds averaging \$411.

However, other important considerations must be weighed when appraising whether, or how, a pre-population program should be offered. A detailed analysis of these issues is beyond the scope of this paper, but we briefly discuss some aspects here. First, any pre-populated return program would require the IRS to receive information returns earlier than it currently does to avoid delays in refunds relative to the status quo in filing deadlines (April 15th). Additionally, IRS staff would have to quickly process and match information returns to generate pre-populated returns. As a result, some of the reduced filing burden among individual taxpayers would be shifted onto information reporters and tax administrators. At present, there are no up-to-date estimates of the costs to the federal government of moving to a tax agency reconciliation system, and previous estimates varied widely (U.S. Department of the Treasury, 2003). Updated technology and improved computing capabilities may lower these costs, and implementing a pre-populated return program could be included in ongoing modernization efforts. The California experience suggests that administrative costs of pre-populated returns at the state level may be cost-effective (Bankman, 2005). Thus a well designed federal program may achieve overall compliance cost reductions.

Second, pre-populated returns may function as a "nudge", encouraging taxpayers to accept the pre-populated returns without adjustment – causing effective tax liability to differ from what it is under current law. This may occur due to the general tendency of individuals to accept default options (Sunstein, 2013) or due to the belief that accepting a pre-populated return might reduce one's audit likelihood. To the extent that current law has been set by Congress to balance various tax policy aims, the new reporting incentives could upset this balance and prompt further changes in tax law, including the introduction of new information returns covering currently unreported items. However, there is reason to believe the nudge effects of pre-populated returns would be small. In particular, since the magnitudes of errors are relatively large when pre-populated returns are inaccurate – with an average understated liability of \$8,800 and an average overstated liability of \$4,200 as reported in Table 2 – the vast majority of such taxpayers may overcome the nudge and make the necessary adjustments. Moreover, the IRS audit regime is, in some sense, orthogonal to the issue of pre-population, as audit probabilities can be established to be independent of whether individuals accept their pre-populated returns.

Nonetheless, it is important to evaluate the potential effect of pre-population on the tax gap, which is currently estimated at around \$600 billion (Hemel, Holtzblatt and Rosenthal, 2021; U.S. Department of the Treasury, 2021). Pre-populated returns could reduce the tax gap by reducing non-filing, incorrect claiming of tax credits, and the under-reporting of income that appears on information returns.

However, since the bulk of the tax gap stems from under-reporting of income *not* appearing on information returns or over-reporting of deductions, pre-populated returns can do little to shrink much of the tax gap. Moreover, pre-populated returns could increase the tax gap if individuals become even less likely to report this income. Experimental evidence suggests that taxpayers may engage in one-sided correction of errors (van Dijk et al., 2020); i.e., they may be less likely to correct pre-populated errors that are in their favor, such as the omission of self-employment income from the pre-populated return. We estimate that, in the extreme, if taxpayers make only favorable adjustments to liability, the tax gap could roughly double under a pre-population regime.

In sum, we find that pre-populated returns have the potential to substantially reduce filing burdens for a large majority of taxpayers using existing information available to the IRS. While implementation details are challenging, we hope that this exploration will inform the discussion of innovative policies regarding pre-populated tax returns.

Tables and Figures

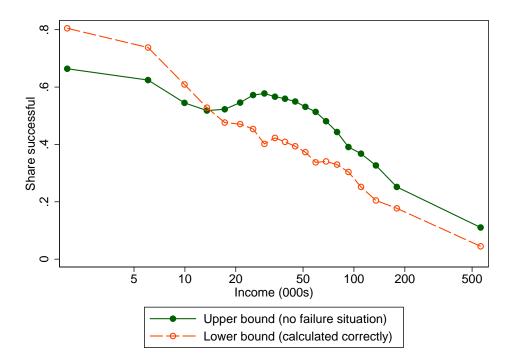

Figure 1: Pre-populated success rates by income

Notes: The figure plots the rate of accurately pre-populated tax returns for the 2019 tax filing population as a function of taxpayer-reported adjusted gross income under each of our two approaches. We use the preferred tolerance thresholds given in column 3 of Table 1. AGI bins are defined by ventiles among the subset of the sample with positive AGI. Taxpayers with zero and negative AGI are excluded from the figure.

Table 1: Pre-population Success rates

	Strictest		Preferred		Least strict
	(1)	(2)	(3)	(4)	(5)
Panel A: Lower bound					
Baseline	0.326	0.370	0.406	0.458	0.552
With known deps. & filing status	0.365	0.414	0.454	0.512	0.612
Tax difference tolerance	\$10	\$50	\$100	\$200	\$500
Panel B: Upper bound					
Baseline	0.432	0.448	0.481	0.509	0.598
With known deps. & filing status	0.476	0.494	0.530	0.562	0.662
Credit tolerance	\$10	\$50	\$100	\$200	\$500
Income/deduction tolerance	\$100	\$200	\$500	\$1000	\$5000

Notes: This table reports the rates at which we are able to accurately pre-populate returns for 2019 tax filers. Across the columns, we relax our tolerance thresholds for defining an observation to have an "accurate" pre-populated return. Panel A shows results for the lower-bound approach, so the relevant tolerance is the acceptable difference between simulated and actual tax liability. Panel B shows results for the upper-bound approach, which requires two separate tolerances: one for failure situations related to credit amounts, and one for failure situations related to income/deduction amounts. Our preferred tolerances are given in the third column. Within each panel, the first row uses the baseline procedure. The second row considers a counterfactual where the IRS has full knowledge of filing status and dependency.

Table 2: Taxpayer characteristics conditional on success/failure

	No failure situation? (upper bound)		Correct calculation? (lower bound)		
	✓ ` · · · · · · · · · · · · · · · · · ·	X	√ `	high	low

Failure situations	0	1	0	1	1
Count (millions)	73.1	78.9	61.7	62.2	28.1

Notes: The table provides mean and median values for 2019 tax unit characteristics conditional on either success or failure of our upper-bound and lower-bound approaches under our preferred tolerance thresholds. Sample weights are used; thus the results are representative of the 2019 tax filing population. The first column describes taxpayers for whom the upper bound approach is successful, while the second column describes those for whom it is unsuccessful. The third column describes taxpayers for whom the lower bound approach is successful. The fourth and fifth columns describe taxpayers for whom the lower bound approach is unsuccessful separated by whether the simulated tax is too high or too low, respectively, relative to reported liability.

Table 3: Pre-population success rates for subsets of taxpayers defined based on 2019 tax returns

	Cumulative share of pop.	Cumulative success rate		Marginal success rate	
	1 1	Lower	Upper bound	Lower	Upper
	(1)	(2)	(3)	(4)	(5)
Narrowest: Single, no dependents, only wages, no unobs. credits/deductions,					
income under \$100k	0.20	0.78	0.82	0.78	0.82
2. Allow married	0.22	0.76	0.80	0.53	0.54
3. Allow dependents	0.30	0.67	0.74	0.41	0.59
4. Add interest/dividends	0.34	0.67	0.75	0.71	0.82
5. Add Social Security	0.36	0.68	0.75	0.76	0.78
6. Add pension/IRA distributions	0.43	0.67	0.74	0.64	0.70
7. Add gambling, UI, state tax refunds	0.44	0.67	0.74	0.54	0.72
8. Add capital gains	0.47	0.66	0.73	0.59	0.60
9. Add high income	0.52	0.64	0.73	0.48	0.68
10. All income types	0.69	0.54	0.60	0.23	0.19
11. Broadest : Eliminate deduction and credit restrictions	1.00	0.41	0.48	0.10	0.22

Notes: This table reports the rates at which we are able to accurately pre-populate returns for certain subsets of 2019 tax fillers. We use our preferred tolerances in Table 1. Subsets are defined based on characteristics from the 2019 tax return. "Unobserved deductions" include all itemized deductions and above-the-line deductions for moving expenses, educator expenses, and health insurance for self-employed persons. "Unobserved credits" are all credits other than the EITC, Child Tax Credit, and American Opportunity Tax Credit. The cumulative success rate (columns 2 and 3) reflects the success rate for all individuals up to and including the row in question. The marginal success rate (columns 4 and 5) reflects the success rate for individuals included in a given row but not the prior row.

Table 4: Pre-populated return characteristics for non-filers

	No filing obligation		Has filing	g obligation
	Mean	Median	Mean	Median
Age	55	59	47	46
Female	0.50	_	0.33	_
Filed a 2018 return	0.11	_	0.38	_
Pre-populated return with dependents	0.02	_	0.11	_
Calculated childless EITC >0	0.082	_	0.049	_
Calculated child EITC or CTC >0	0.007	_	0.103	_
with revealed dependents	0.008	_	0.108	_
Calculated AGI	1,183	0	56,771	36,600
Calculated AGI (if potential refund)	3,908	2,900	40,805	28,600
Tax withholding	37	0	4,621	1,700
Tax withholding (if >0)	261	100	5,585	2,400
Has potential refund	0.17	_	0.43	_
Has potential taxes owed	0.00	_	0.55	_
Potential refund (if >0)	387	200	1,528	900
Potential taxes owed (if >0)	_	_	5,077	1,500
Count (millions)	46.3		8.8	

Notes: The table describes a 0.1% random sample of non-filers: individuals between the ages of 18 and 105 who are neither a primary nor secondary filer of a 2019 tax return and who have a 2019 information return with a U.S. address. We exclude individuals who filed jointly in 2018 if their spouse filed a 2019 return. Otherwise we construct tax units based on the 2018 filing, assuming single status if no 2018 return was filed. In the table, individuals are classified by whether there is an apparent filing obligation, i.e., whether simulated AGI is greater than the standard deduction for singles (conditional on age). All rows present results using our baseline specification except for the row showing the prevalence of potential EITC or CTC credits based on "revealed" dependents: those that are claimed by the individual either in 2018, 2020, or 2021 and not claimed by a 2019 filer. Sample weights are used; thus the results are nationally representative. Medians of dollar-denominated variables are rounded to the nearest \$100.

A Additional details

In this appendix, we provide additional details on the assumptions we make in our upper and lower bound calculations. We also discuss additional results shown in the appendix tables and figures.

A.1 Further details on procedure

Throughout this paper, the baseline procedure that we consider is the following:

- The IRS observes filing status, dependents, and tax unit individuals based on the prior year (2018, in our case) return. By "tax unit individuals", we mean the one or two individuals that are the primary and secondary filers.
- 2. The IRS prepares a current-year (2019, in our case) return for that tax unit based on the information returns received by the tax unit individuals in the current year. The IRS assumes that dependent status is unchanged from year to year, except for mechanical aging-out effects.²¹

A.1.1 Tax unit composition

In our empirical approach, we begin with the set of current-year tax units, as that is the sampling frame of the SOI file that we use throughout the paper. In the case of a tax unit where the 2019 tax unit individuals does not match the 2018 tax unit individuals – e.g., in the case of marriage, divorce, death, etc. – this creates an upper bound failure situation. In such cases, the IRS would have prepared a return that includes the wrong people. We do not attempt the lower bound direct computation in these cases. Rather, we code this as an immediate lower bound failure.

A.1.2 Non-filers

The universe of non-filers under consideration in our non-filer pre-populated return exercise includes the union of two sets:

- 1. "Single" non-filers: Individuals who (1) received any information return in 2019 with an address in the 50 states or the District of Columbia, (2) did not file in 2019 and (3) were either non-filers in 2018 or filed in 2018 using any status other than married filing jointly. If the individual was a non-filer in 2018, we assume that the IRS would prepare a single return for that individual in 2019. If the individual was a filer in 2018, the IRS would use the filing status on their 2018 return.
- 2. "Married" non-filers: These are married couples where (1) either member of the couple received any information return in 2019 with an address in the 50 states or the District of Columbia, (2) they filed jointly in 2018, and (3) neither member of the couple was a filer on any return in 2019. We assume that the IRS would prepare a married-filing-jointly return for these tax units.

We ignore the set of 2019 non-filers not included in either of these sets. One component of those excluded include individuals who do not receive information returns. Additionally, we exclude situations where a married couple filed jointly in 2018, but exactly one member of the couple filed a return in 2019. Among those that receive information returns, we estimate that there are approximately 400,000 such individuals that fit this second condition.

²¹See Section A.1.3 for further discussion of dependents.

A.1.3 The treatment of dependents

For the upper bound approach, we identify the set of individuals predicted to be a dependent of a given tax unit in 2019, as well as the set of individuals predicted to be an EITC dependent of a given tax unit in 2019. We refer to the former as an "apparent 2019 dependent" and the latter as an "apparent 2019 EITC dependent." Apparent 2019 dependents are those who were dependents in 2018 and are any age other than 23 in 2018. For those tax units that claimed the EITC in 2018, then apparent 2019 EITC dependents are dependents actually claimed in 2018 for EITC purposes. For those tax units that did not claim the EITC in 2018, then all 2018 dependents who are younger than 18 in 2019 are apparent 2019 EITC dependents.

A given tax unit will trigger the dependent mismatch failure situation if the merge between actual 2019 dependents and apparent 2019 dependents is less than perfect – i.e., if there is an actual 2019 dependent that is not an apparent 2019 dependent, or vice versa. A given tax unit will trigger the EITC dependent mismatch failure situation if (1) they claim the EITC in 2019 and (2) the merge between actual 2019 EITC dependents and apparent 2019 EITC dependents is less than perfect. Because it would require an amendment of the pre-populated return, we count it a failure situation if the identities of the dependents do not match, even if the total count of (EITC) dependents matches.

In contrast, for the lower bound approach, we calculate only the *number* of apparent 2019 dependents, as well as the number of dependents eligible for the CTC, and the number of dependents eligible for the EITC. The apparent 2019 dependent follows the same procedure as the upper bound approach. For tax credit eligibility purposes, we use a purely age-based threshold: a 2018 dependent is assumed to be a 2019 dependent unless he or she attains age 24 in 2019 and if an apparent dependent is under the age of 17 (18), we deem them to be eligible for the CTC (EITC).

A.2 More detail on upper bound failure situations

In this section, we define each of the upper bound failure conditions that are not self-explanatory. The full set of failure situations is included in Table A2, which shows their likelihood of occurring. The most common failure situations are Schedule C mismatches (16 percent of taxpayers), followed by itemized deductions (11 percent), wage mismatches (9 percent), taxable pension/IRA mismatches (7 percent), and Schedule E rents and royalty mismatches (7 percent). The least common failure situation is an early distribution from a Roth IRA (0.5 percent). Overall, just over half of taxpayers have any failure situations, and the majority of these taxpayers have only one.

Figure A1 shows how the prevalence of the most common six types of failure situations vary by income. Itemizing is not a prevalent source of failure until AGI reaches about \$50,000, above which point the likelihood of itemizing rises rapidly. In contrast, the presence of Schedule C income is common at many income levels and is non-monotonic in income. Schedule C income is common for tax units earning \$10,000-\$20,000 and then falls in prevalence before rising again, reflecting the bunching of self-employed taxpayers near the first EITC kink (Saez, 2010; Mortenson and Whitten, 2020). Mismatches between reported wages and Form W-2 amounts are also non-monotonic, reaching a peak around \$10,000 and a nadir around \$100,000. Rents and royalties are less common than itemizing but otherwise follow a similar pattern; they are less common below \$50,000 and their prevalence rises linearly with log income above \$50,000.

Dependent mismatch and EITC dependent mismatch: see Section A.1.3, above.

Change in filing status: This failure situation is triggered in a number of cases. First, it is triggered

when the identity of the tax unit (its primary and secondary filers, without regard to who is primary) is not constant from 2018 to 2019 – e.g., when the tax unit is a married couple in 2019 but two singles in 2018. Second, this failure situation is triggered when the 2018 filing status of the tax unit does not match the 2019 filing status (e.g., due to a change from single to Head of Household, or vice versa). An important exception is that a taxpayer who files as unmarried in 2019 and was a non-filer in 2018 does not trigger this failure situation.

Form 1099-R with taxable amount not determined: This situation is triggered when a taxpayer receives a Form 1099-R in 2019 (other than from an IRA) with box 2b checked, indicating that the taxpayer needs to perform additional calculations (not fully observable to the IRS) in order to calculate the taxable amount.

Certain above-the-line deductions: These refer to the deduction for moving expenses, self-employed health insurance, and educator expenses.

Section 199A deduction complications: Under section 199A, taxpayers are generally entitled to a deduction for 20% of qualified business income. However, there are several limits to this deduction that are not fully observable to the IRS, such as high-income taxpayers whose income is derived from a specified service trade or business (SSTB). This failure situation is triggered whenever a high-income individual's reported Section 199A deduction differs from our calculated value.²²

Residential energy credits: This refers to the taxpayer claiming credits on line 5 of Form 1040, Schedule 3.

Early distribution from Roth IRA: This failure situation is triggered if the taxpayer receives a Form 1099-R with distribution code J in box 7. This is a failure mode because the taxable amount of such a distribution depends on the taxpayer's basis in the Roth IRA, which is not observed by the IRS.

Schedule C income does not match Form 1099-MISC NEC: This condition can arise for many reasons. First, the taxpayer may have small business income that is not included on a Form 1099-MISC. Second, the taxpayer may have expenses that are correctly deductible on Schedule C but of course are not observed by the IRS. Third, the taxpayer may fail to report 1099-MISC income on Schedule C.

Itemized deductions in 2019: This is a failure situation because most itemized deductions – in particular, neither state/local taxes paid nor charitable contributions²³ – are not covered by information returns. Over 99.5% of itemizers claim at least one of these two deductions.

Wages do not match Form W-2 wages: This could occur for a variety of reasons; the following is a non-exhaustive list. First, the taxpayer may (intentionally or otherwise) misreport. Second, the Form W-2 itself could be erroneous – perhaps because we have identified the "wrong" W-2 in the case of duplicates. Third, the taxpayer could have unreported tip income. Fourth, the taxpayer could have received a disability pension distribution prior to their firm's retirement age. Fifth, the taxpayer could have received a taxable scholarship.

Taxable pension/IRA income does not match Form 1099-R: We assume that the IRS would prepopulate a return treating the entire distribution amount (with Box 7 codes 1, 2, or 7) as taxable. A mismatch between this amount and the taxpayer-reported amount could occur for a variety of reasons; the following is a non-exhaustive list. First, this failure condition is often an implication of the "taxable about not determined" failure mode – which often reflects the fact that some of the distribution

²²An additional limitation on the 199A deduction arises because the deduction is limited to 20% of ordinary taxable income, which is often binding for lower-income taxpayers. We do not consider mismatches arising from this limitation a 199A failure because any other failure situation resulting in the wrong ordinary taxable income would flow into this calculation.

²³The IRS observes state income tax withheld on certain information returns, but it does not observe property tax paid nor any amount of state tax paid directly.

represents basis recovery and thus not all of the distribution is taxable. Second, the distribution could comprise the distribution part of an indirect rollover (e.g., from a 401(k) to an IRA), which is correctly non-taxable. Third, the taxpayer may (intentionally or otherwise) misreport. Fourth, the Form 1099-R itself could be erroneous.

Lifetime Learning Credit: In general, post-secondary education expenses can give rise to one of two credits (but not both): the American Opportunity credit (AOC) or the lifetime learning credit (LLC). If a taxpayer is eligible for both, the AOC dominates the LLC. We assume that a pre-populated return would generate an AOC in the presence of education expenses. However, the AOC has additional restrictions relative to the LLC – most notably, the AOC can be taken only with respect to expenses for the first four years of post-secondary education. Additionally, a taxpayer may not claim the AOC if she has been convicted of a drug-related felony. These conditions are not directly observed by the IRS. Thus, if the taxpayer is observed to claim the LLC instead of the AOC (presumably due to one of the conditions mentioned above), this would cause a discrepancy between the pre-populated return and true liability. Thus, we treat it is as an upper-bound failure situation.

A.3 Additional Tables and Figures

The characteristics of the sample are shown in Table A1, weighted to represent the tax filing population of 152 million tax units. A little over a third of filers are married and nearly a third have dependents and claimed the CTC. Pre-populated returns may limit the need for using a paid preparer, which around half of taxpayers did in 2019. Median AGI in the sample is \$41,200, median taxable income is \$24,100, and median tax liability is \$1,800. All three measures are skewed in the sample with much larger means than medians.

A.3.1 Success rates by age

Figure A2 shows how our upper and lower bound estimates for the share of pre-populated returns that are successful vary by age. The upper bound success rate starts at over 80 percent for 18-year-olds but falls steadily to around 40 percent for 36-year-olds. It stays relatively flat across the age distribution from there. The lower bound success rate starts around 90 percent for 18-year-olds and falls even more sharply than the upper bound, reaching around 30 percent for 36-year-olds. It stays low until about age 45, above which the estimate climbs steadily until plateauing at around 45 percent for ages 70 and above.

A.3.2 Over- vs. understated liability

Figure A3 breaks out our lower bound estimates by whether the pre-populated return under- or overstates liability. In panel (a) we see that, in all income bins except for the top five percent, pre-populated returns are more likely to overstate liability than to understate it. Panel (b) further illustrates that for most income bins, the average magnitude of the error is fairly small: below \$5,000. Panel (c) shows these error magnitudes relative to income. We see that, in the bottom income decile, liability is overestimated by a sizeable share of income: over twenty percent. But for most taxpayers, the average error in pre-populated liability is less than five percent of income.

A.3.3 Success rates line by line

In Table A3 we report the success rate for pre-populating key lines of the 2019 Form 1040. Following our baseline upper bound approach, for income lines we use a tolerance of being within \$500 and for credits we use a tolerance of \$100. Column (1) shows the share of taxpayers where the pre-populated returns match the actually-filed returns, including cases where both are zero. This represents the share of individuals who would need to make no corrections to that line. In column (2), we restrict attention to those observations where the line on the actually-filed return is nonzero, which speaks more directly to the relative accuracy of our procedure for that line. The wage line is pre-populated accurately for 92% of taxpayers, including 90% of those who report wages on their tax return. Conditional match rates are similar for taxable interest and qualified dividends, but the unconditional match rates are higher due to the presence of many zeros. Conditional match rates are somewhat lower for pensions (81%) and are much lower for capital gains (44%) and Schedule 1 income (23%), a category that includes Schedule C (sole proprietor) income, Schedule E income (rents, royalties, S corporation income, and partnership income), unemployment compensation, and other less common income types.

A.3.4 Success rates by prior-year characteristics

Table A4 repeats the analysis of Table 3 except it defines taxpayer subsets based on 2018 characteristics. That is, we are imagining that the IRS is pre-populating 2019 returns for a set of filers based on their 2018 returns. The narrowest subset again restricts to those who are single, with no dependents, whose only source of income is wages, and have no unobserved credits or deductions; however, in this table these determinations apply to the 2018 data, not 2019. Around 17 percent of 2019 filers satisfy these 2018-based restrictions. Among this group, we find that between 69 to 77 percent of 2019 pre-populated returns would be successful.

The success rates in Table A4 are universally lower than in Table 3 except in the final row, where they are mechanically equal. The success rates are five (upper bound) and nine (lower bound) percentage points lower in the narrowest subset. The five percentage point upper-bound gap remains relatively stable through row 8 (adding capital gains), while the nine percentage point lower-bound gap reduces to five percentage points. Both gaps shrink to two percentage points when we allow all income types. In sum, requiring taxpayers to provide categorical information prior to a pre-populated return has a modest effect on accuracy rates. This result is similar to our result from Table 1 that shows that if taxpayers provided the IRS updated information about filing status and dependents prior to pre-population overall success rates would increase by around five percentage points. Policymakers contemplating these options would need to weigh the increases in accuracy against the additional burdens faced by taxpayers.

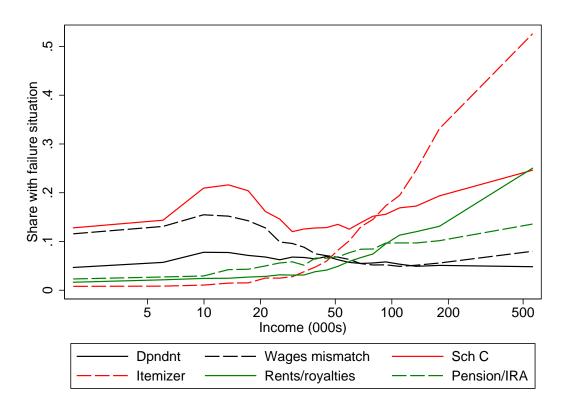

Figure A1: Pre-population success by Income by Situation

Notes: The figure plots the rate of certain common failure situations for the 2019 tax filing population as a function of taxpayer-reported adjusted gross income. We use the preferred tolerances, given in column 3 of Table 1. AGI bins are defined by ventiles among the subset with positive AGI and include two additional bins for taxpayers with zero and negative AGI (not shown). Additional detail on certain failure situations is given in Appendix A.2.

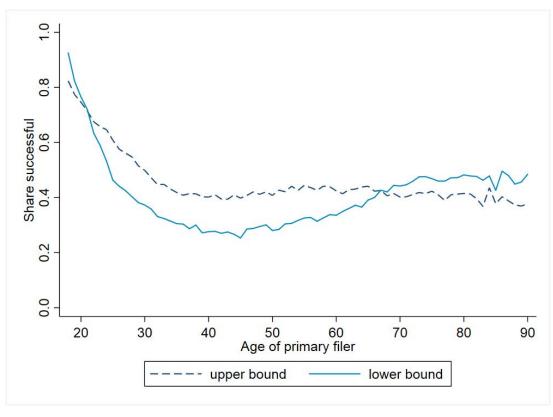

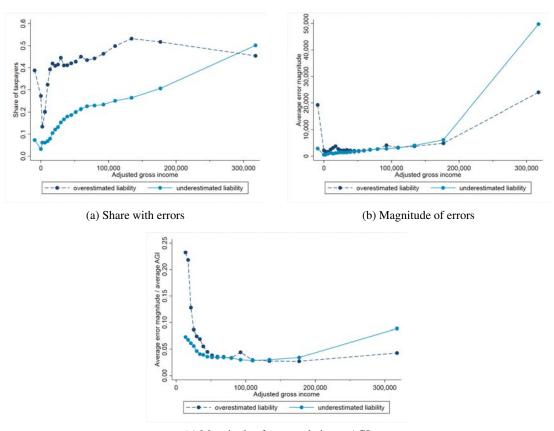

Figure A2: Pre-population success rates by age

Notes: The figure plots the share of tax year 2019 pre-populated returns that would be within our preferred tolerance levels for accuracy under our upper-bound and lower-bound approaches, by primary filer age. Sample weights are used; thus the results are representative of the 2019 tax filing population. Age is censored at 18 and 90.

Figure A3: Lower bound direction and magnitude of liability errors

(c) Magnitude of errors relative to AGI

Notes: The figure plots information for two subsets of the 2019 tax filing population: those for whom the difference between their simulated pre-populated tax liability and reported liability exceeds \$100, and those for whom the difference is negative and exceeds \$100 in magnitude. Panel (a) plots the share of each group by AGI bin. Panel (b) plots the average magnitude of the difference between the simulated pre-populated tax liability and the reported liability within AGI bin for each group. Panel (c) plots the averages error magnitudes of panel (b) divided by average AGI within each AGI bin. Sample weights are used; thus the results are representative of the 2019 tax filing population. Data points are shown at the median AGI within each AGI bin. AGI bins are defined by ventiles among the subset with positive AGI and include two additional bins for taxpayers with zero and negative AGI. Panel (c) only reports bins with average AGI exceeding \$10,000 – the top 17 ventiles.

Table A1: Summary statistics

	Mean	Median
Primary filer age	45	43
Married	0.37	_
Has dependents	0.32	_
Dependents	0.57	0
Uses paid preparer	0.51	_
Claims Earned Income Credit	0.17	_
Claims Child Tax Credit	0.30	_
Adjusted gross income	76,650	41,200
Taxable income	59,083	24,100
Tax liability	9,598 1,800	
Count (millions)	152.0	

Notes: The table describes our sample of 2019 tax units from the Statistics of Income. Sample weights are used; thus the results are representative of the 2019 tax filing population. For dollar-denominated variables, medians are rounded to the nearest \$100.

Table A2: Share with each upper bound failure situation

Situation	Share with this failure situation	Share with <i>only</i> this failure situation
	(1)	(2)
Schedule C income does not match 1099-MISC NEC	0.162	0.075
Itemized deductions in 2019	0.109	0.040
Wages do not match W-2 wages	0.089	0.050
Taxable pension/IRA income does not match 1099-R	0.067	0.017
Sched E rents/royalties (except from K-1)	0.065	0.014
Dependent mismatch from 2018 to 2019	0.061	0.019
Child/dependent care credit	0.039	0.017
Capital gains income does not match 1099-B	0.036	0.008
S corp/partnership income does not match K-1	0.034	0.003
Change in filing status from 2018 to 2019	0.034	0.012
1099-R with taxable amount not determined	0.033	0.003
EITC dependent mismatch from 2018 to 2019	0.029	0.006
Interest does not match 1099-INT	0.028	0.006
Certain above-the-line deductions	0.023	0.001
Dividends do not match 1099-DIV	0.021	0.005
Section 199A deduction complications	0.020	0.000
Lifetime learning credit	0.014	0.008
Residential energy credits	0.011	0.004
Schedule F income	0.010	0.003
Noncapital gains (Form 4797)	0.009	0.000
Received or paid alimony	0.005	0.002
Early distribution from Roth IRA	0.005	0.000
Any failure situation	0.519	
Precisely one failure situation	0.293	

Notes: The table reports the share of tax units that have each failure situation in the 2019 tax filing population. We use the preferred tolerances, given in column 3 of Table 1, Panel B. Column (1) provides the share of tax units with each failure situation; the table is sorted in descending order by column (1). Column (2) provides the share of tax units who have the given failure situation and no other failure situation. The bottom row gives the share of tax units with at least one failure situation. This table includes the full set of failure situations we identify. Additional detail on certain failure situations is given in Appendix A.2.

Table A3: Success rate for selected lines on Form 1040

Line	Unconditional match rate	Conditional match rate
	(1)	(2)
Wages	0.918	0.903
Taxable interest	0.970	0.919
Qualified dividends	0.977	0.905
Income from Sch. 1	0.700	0.241
Taxable IRA and pensions	0.929	0.806
Capital gains	0.893	0.442
AGI	0.507	-
Taxable income	0.521	-
EITC	0.892	0.455
Child tax credit	0.856	0.628

Notes: This table reports the match rates for several lines on Form 1040. Column (1) reports the share of observations with a non-zero value on the relevant line. In column (2), among this subset, we calculate the share of observations whose values derived from information returns matches the amounts reported on Form 1040. In the rows marked "AGI" and "taxable income", we do not make the restriction to non-zero values. In all rows, we restrict to the set of tax units whose composition remained constant from 2018 to 2019. We use a tolerance margin of \$500 in all rows, except that we use a tolerance margin of \$100 in the EITC and the Child Tax Credit rows. For the purpose of this table, the Child Tax Credit includes both the refundable and non-refundable part aggregated together.

Table A4: Pre-population success rates for subsets of taxpayers defined based on 2018 tax returns

	Cumulative share of pop.	Cumulative success rate		Marginal success rate	
		Lower	Upper bound	Lower bound	Upper bound
	(1)	(2)	(3)	(4)	(5)
Narrowest: Single, no dependents, only wages, no unobs, credits/deductions,					
income under \$100k	0.17	0.69	0.77	0.69	0.77
2. Allow married	0.26	0.67	0.71	0.63	0.61
3. Allow dependents	0.35	0.60	0.68	0.39	0.57
4. Add interest/dividends	0.37	0.60	0.68	0.61	0.74
5. Add Social Security	0.42	0.62	0.69	0.73	0.75
6. Add pension/IRA distributions	0.44	0.61	0.68	0.58	0.58
7. Add gambling, UI, state tax refunds	0.47	0.61	0.68	0.52	0.66
8. Add capital gains	0.48	0.61	0.68	0.57	0.58
9. Add high income	0.53	0.59	0.67	0.42	0.58
10. All income types	0.69	0.52	0.58	0.27	0.26
11. Broadest : Eliminate deduction and credit restrictions	1.00	0.41	0.48	0.16	0.27

Notes: This table reports the rates at which we are able to accurately pre-populate returns for certain subsets of 2019 tax filers. We use our preferred tolerances in Table 1. Subsets are defined based on characteristics from the 2018 tax return. "Unobserved deductions" include all itemized deductions and above-the-line deductions for moving expenses, educator expenses, and health insurance for self-employed persons. "Unobserved credits" are all credits other than the EITC, Child Tax Credit, and American Opportunity Tax Credit.
